MSS. intended for publication and books, etc., intended for review should be sent to the responsible editor, Professor J. McKeen Cattell, Garrison-on-Hudson, N. Y.

*EDWARD ORTON, EDUCATOR.**

I RESPOND this afternoon to a summons difficult to obey but impossible to deny. I am reluctant to undertake what could be done so much better by others, but it is impossible for me to decline to join in doing honor to the memory of one whom I so much loved and admired, however feeble and inadequate my words may be.

My association with Dr. Orton extended through a period of nearly thirty years. Beginning as a casual acquaintance, such as is common among men engaged in the same occupation, it rapidly ripened into a friendship which, happily for me, grew in strength with the years as they passed. My most intimate personal relations with him existed during the earlier years of the Ohio State University, the institution to which he gave so large a share of his life's work, and which to-day makes fitting acknowledgment of the value of that work and of the irreparable loss which it has sustained in his death. Of Dr. Orton as one of the most eminent of geologists of his time, of the splendid example which he set in the performance of the duties of plain citizenship, and of the many other striking characteristics of a career which is rarely paralleled, others will speak, and I will re-

*Read at a Memorial Meeting, Columbus, Ohio, November 26, 1899. A portrait of Orton was published as a frontispiece to the issue of SCIENCE for September 1, 1899.

strict myself, therefore, to remarks upon his earlier work in this university and his influence as an educator rather than as a specialist.

I firmly believe that no one can fully understand and fairly evaluate Dr. Orton's services to the university during the first ten years of its existence who was not himself in some way or other a part of its official organization during those years, and in close touch with methods and motives by which its future career was determined, and I must ask your indulgence in a brief statement of some of the conditions under which the institution came into existence.

The Act of Congress which created this and many other noble institutions of learning, having been passed in the most discouraging and gloomy year of the great Civil War, did not receive immediate consideration and acceptance by many of the States, and in Ohio there was a delay of nearly ten years before those interested saw definite promise of the actual realization of their hopes. In the meantime and during the latter part of this period there was much necessary and useful discussion in regard to the character and scope of the proposed school. Innumerable schemes for utilizing the prospective income were thrust upon the public, and there was much strength in support of a division of the fund among several existing institutions. The first board of trustees courageously resisted all attempts to destroy by disintegration, and it was finally determined that the institution should be located at Columbus and known as the Ohio Agricultural and Mechanical College.

The field of controversy was now greatly narrowed, but was, perhaps, correspondingly more intense. The character of the work of the new school, the scope of its courses and their relation to the requirements of a liberal education were yet to be determined. On the one hand were those who urged a generous interpretation of the Act of 1862, and who believed that it was primarily intended to furnish the foundation of an institution which might in time become a great university for all of the people; that while, in the provisions of the Act the nation had determined to fortify and invigorate the two great sources of the State's material prosperity, agriculture and manufactures, especial emphasis had also been placed upon the importance of fostering the more purely intellectual or culture components of a well-rounded course of study, for it was specifically directed that these must not be neglected. On the other, was a considerable group of men, equally honest, conscientious and well meaning, who wished to organize a school, intensely practical in tone and atmosphere, in which even science would have found no place except as applied science, and which would have offered little opportunity to those—and, fortunately, they are many—who seek to show their right to labor in the higher regions of more purely intellectual activity. Both sides of this most important controversy were represented by strong men in the first board of trustees, and it is but justice to all to say that the conflict was waged in a manner worthy of the dignity of the occasion and of the great trust for which they had become responsible. I cannot here even refer to the various phases of this discussion or to those who were most active and influential in shaping the organization of the school, nor can I omit saying that to the first president of the board of trustees, Valentine B. Horton, and to Joseph Sullivant, then and long one of the leading citizens of Columbus and of Ohio, the University will ever be indebted for the exercise of a courage, tact and unwearying effort that went far to put the institution in the way of being what it has been, is, and is sure to be in the future. Fortunately, they were supported by many others of the board, who, in themselves, represented liberal culture, combined with a genuine democracy of feeling and a loyalty to the Commonwealth, compelling the belief that nothing was too good for the children of the people.

The issue was made and met in the appointment of the first faculty of instruction; and in the selection of the first presiding officer fortune was singularly favorable to the new school. A professor in a New England college who has received the highest political honors his State could confer upon him had been invited to become the president of the college, but circumstances arose which made his acceptance impossible. Dr. Orton had been in Ohio only a few years, but he had become widely and well known, not only on account of his accomplishments as a geologist, but as well by his charming personal qualities, and he had been already chosen to fill the chair of geology. To him the trustees now turned, and he reluctantly consented to be the first president of the Ohio Agricultural and Mechanical College. I say reluctantly, for it was well known among his friends and associates that he was loath to assume administrative duties which must necessarily interfere with the continued pursuit of his specialty in which he was already recognized as an authority. Happily for the institution he yielded his personal preferences, and for eight years he was at once president and professor.

Among the several thousand young men who crossed college thresholds in Ohio in the autumn of 1873 seventeen entered the building in which we now are, and enrolled themselves as students, the first of the many thousands who have since followed their example. I cannot describe and few can appreciate the many trials and difficulties of those earlier years. The institution was practically unknown, even among those from whom its patronage was most likely to come. It stood for a new departure in education which was just entering upon its experimental stage, and with few exceptions it was looked upon with suspicion by other colleges in the State. The members of its first faculty, of whom only four are now living, were mostly young men, full of ambition and enthusiasm for their work and thoroughly in harmony with the spirit of the time, for even then had come the dawn of the marvelous last quarter of the wonderful nineteenth century, a period during which, short as it is, the relation of man to the material universe to which he belongs has undergone a far greater change than in any other period in history. It is often, indeed generally, possible in looking backward upon things accomplished to see many mistakes that might have been avoided and many opportunities not properly utilized. As I review, however, the principal events of Dr. Orton's presidency of this institution I am at a loss to say, even with the better knowledge that accompanies retrospection, how the many emergencies that presented themselves could have been met more wisely. To begin with, his standard of educational work was of the highest type. He fully realized that the success of the institution depended on the establishment and maintenance of a standard of scholarship so high as to compel the respect of the best educational forces not only at home but abroad. Himself a scholar in the broadest, best and most exacting sense, he encouraged faculty and students to seek the best ideals, and no one of them who gave the slightest indication of the possession of the *divine afflatus* in learning ever failed of appreciative recognition from him. He believed that the character of an educational institution should be judged by the quality of its work rather than by the number of students enrolled in the annual catalogue, a principle which everybody admits and nearly everybody ignores. To stand up for it and do it, especially during the early struggling years of a college, demands a courage that few possess. That Dr. Orton did this, even under the most trying conditions, I set down as, on the whole, the most notable characteristic of his career as president. For I am thoroughly convinced that if he had chosen to do otherwise, if the doors had been opened wide, at both ends of the curriculum, the institution would have long since sunk into a deserved oblivion.

Few college presidents have so continuously received the loyal support and sympathy of their colleagues in the faculty as did Dr. Orton. A college faculty is not likely to shine as an example of meek and amiable submissiveness, and this is particularly true of one composed, as this was, and many are to-day, of specialists. Twenty-five years ago, and earlier, it was usually believed that a college professor might fill any chair that happened to be vacant, and indeed more or less regular interchange of duties was often regarded as highly desirable. The passing of the era is to be attributed in a large measure to the example and influence of institutions of which this is a type. The specialist, however, is tolerably certain to hold that his own particular department is of far greater importance than any other, and he may be relied upon to desire and demand a large share of available resources to aid in its development. Upon the president falls the by no means agreeable task of apportionment and restraint, and this duty was discharged by Dr. Orton with rare discrimination, fairness and tact. No mere administrator, however skilled in that capacity, could have done as well. His scholarship was thorough and yet broad enough to enable him to know what was being well or indifferently done in every department, and is there not a freemasonry among scholars which makes mutual recognition easy even when there is no common language? I am reluctant to refer to my own personal experience on an occasion which is completely filled with one personality; but I can never forget the many instances in which I received from him encouragement in the way of sympathetic acknowledgment and often praise, for work which was doubtless trivial and unimportant, but the recognized success of which served to keep alive the fires of ambition, enthusiasm and interest.

Of Dr. Orton's relations to the students, whose numbers multiplied many times during his presidential period, it is hardly necessary to speak. Too often the president of a college is unfortunate in that he rarely comes in close relations with students except to administer reproof or define restraint. The discipline of this college in its early years was nearly as great a departure from accepted traditions as were its methods of instruction. A large degree of freedom was allowed without the asking, but the line separating liberty from license was sharply defined. It was intended to cultivate a spirit of manly self-reliance together with a full knowledge of the responsibilities of citizenship, and the administration of the few simple regulations was always so just and fair that no ground for complaint could be found. In this as in all his relations with others Dr. Orton believed in the efficacy of reason and in the doctrine that it is generally more important to convince a young man that he has done wrong than to punish him for so doing. He was slow to condemn and reluctant to punish, but I have known few men more inflexible and unflinching when a vital principle was contested. He won the confidence of all with whom he came in contact, and young and old valued his judgment, and advice. As a teacher he was most inspiring. His literary and linguistic powers were unusual, and he easily made any topic attractive, even to the dull. From hundreds of his pupils comes the testimony that to him they owe the first quickening of their intellectual life, the earliest revelation of their own moral obligations and responsibilities. There can be no higher praise than this.

Complete as was Dr. Orton's success in everything concerning the internal management of the college, his services as its representative in all its relations to the outside world were of far greater importance. The young institution was but coldly received at first, and this was especially true among those who ought to have been its friends. There were numerous harsh and unjust criticisms of its course of study, its faculty, its board of trustees, and it was even attempted by a few men of influence to make it a football of partisan politics, so that its organization might be completely changed with every change in State administration. Against these and many other adverse conditions its board of trustees, president and faculty had to contend. The confidence of the people had to be won and was won, largely by the strenuous but tactful efforts of the president. An eloquent exponen tof the progress of scientific thought, in more departments than one, Dr. Orton was everywhere welcome upon the lecture platform. In cities, towns and villages, in grange and farmers' institute, in teachers' convention and literary society, whenever men and women met to foster intellectual growth, he was heard with delight and approbation. His speech was choice, yet simple, clear and dignified, often rising to an eloquence, never of sound or mere words, but of noble thought. Fortunate, indeed, was the new college in having so splendid an exponent, and it is not strange that gradually but surely there came to its support a large and influential constituency from among the best people of the State.

Nor was there any lessening of his influence in its behalf when, after several attempts and against the wishes of the friends of the college, he induced the board of trustees to relieve him of administrative duties and allow him to devote his entire time to his professorship. After that time much of his most important scientific work was done, and as State geologist he became, even more than before, familiar with every nook and corner of the State. His broad democracy of spirit and his generously helpful disposition combined to put him in close touch with the great industrial interests of Ohio, including man as well as matter. He knew the miner as well as the mine, and it would be difficult to measure the value to the university of his almost unique relations with the productive forces of the Commonwealth. The beautiful and noble building which bears his name, and which, from this time on, will stand as a monument to his memory, bears witness, in the very stones of which it is composed, of the readiness with which these forces responded to his touch.

But still more enduring will be the traditions of his life and work in and about this institution, his charming personality, his felicitous speech, his lofty moral and intellectual ideals.

His title to high, perhaps highest, place among the great benefactors of the university, those who by wisdom and tact first made its existence possible and afterward its destruction forever impossible, rests upon a foundation as solid as that of the rocks he so much loved.

" Say not of me that I am dead," were the last words of a great English poet; " Say not of him tha the is dead " are our words to-day; speaking for the few who have been privileged to enjoy the most intimate personal friendship, as well as for the many, scattered over this broad land; for all our lives have been better and will be better because of their having intermingled with his.

Worcester Polytechnic Institute.

EDWARD ORTON, GEOLOGIST.*

It was in the autumn of 1869, just thirty years ago, that I first met Dr. Orton. In that year the Second Geological Survey of the State was inaugurated under the directorship of the late Professor Newberry; Governor Hayes named Dr. Orton as one of the two principal assistants for which the law made provision; and it was my own privilege to be accepted, at the same time, as a volunteer aid. In the arrangement of duties Dr. Orton took charge of work in the southwest quarter of the State, and Dr. Newberry gave chief attention to the northeast quarter. Being assigned to Newberry's corps, I had no opportunity to meet Dr. Orton until late in the season, when I had the good fortune to be bidden to attend a conference of the chiefs at Columbus. While on the journey from Cleveland, Newberry prepared me for the meeting by sketching the quality and character of his colleague—a man without guile, direct in his conversation, and absolutely transparent as to motive. The simplicity of manner which would impress me at the start was not of manner merely, but was a fundamental trait coördinate with, and not contradicted by the wisdom which made him a man of affairs. His sensitive conscience making him peculiarly careful to adhere to the facts of observation, he was cautious and conservative in all his geologic work.

Newberry's description naturally made a strong impression, and in the conference that followed it is probable that I gave as much attention to the man as to the subjects of discussion. Certain it is, that the geologic themes have vanished from my memory, while the picture of the man remains. In later years, as we met from time to time, as I listened to his voice in public address or read the papers that emanated from his pen, I was able to add here and there a detail which Newberry's sketch had failed to delineate, but no line of it was ever erased, and Orton has remained for me one of the safest and most open-minded of investigators and the simplest, kindliest, and most lovable of men.

To what extent considerations of historical fitness may have determined the arrangement of to-day's exercises I do not know, but certainly there was peculiar propriety in giving first place to Orton's work as an educator. During the first half of his period of intellectual activity education was the primary theme, and it was only in later years that geology assumed prominence. We are told that his first geologic observation was undertaken with the distinct purpose of increasing his efficiency as a teacher of geology, and in his early acquaintance with rocks and fossils his point of view was educational. Interest in geologic studies for their own sake was a matter of development, and many years elapsed before it assumed control in the determination of his fields of activity. This peculiarity of his introduction to the science in which he finally achieved distinction had much to do with the quality of his scientific work and scientific writings.

It determined, in the first place, that he should not specialize at the beginning of his career. In geology, as in medicine, there are general practitioners, broadly versed in the principles and particulars of the science, who are prepared to undertake and conduct investigations of great variety; and there are specialists, each devoted to some minor branch of the general subject, in which he works intensely and exhaustively. The specialist, restricting his attention thus to

* Read at a Memorial Meeting, Columbus, Ohio, November 26, 1899.

a narrow field, is almost necessarily a somewhat narrow man, and while his concentration of effort may lead to important results altogether unattainable by the general student, he is subject to great danger from lack of balance. The teacher of geology is compelled by his vocation to acquaint himself with all branches of the science, so that his view is necessarily broad, and if he is also an investigator in a special field he is comparatively exempt from the recognized dangers of specialization. Orton's early work as teacher and observer gave him the broad view. When he first became known to the scientific world as an investigator he was recognized at once as a general practitioner or all-around geologist, and when, in later years, his field was somewhat restricted and he became an expert in a special department, there was no danger that his narrow view would blind him to the recognition of the broader relations.

In somewhat similar way the method and phraseology of his scientific writings were determined by the compound character of his career. As a teacher he was called upon to present the principles of his science to beginners in scientific study; as a lecturer to popular audiences he was accustomed to the communication of scientific ideas in untechnical language; and as executive officer of academy, college and university he had constantly to deal with men of affairs untrained in the technicalities of science. Thus ever in touch with the lay mind he was in no danger from the literary pitfalls which beset the recluse and the specialist. He wrote for the people in language which they could understand, and even when presenting his scientific conclusions to brother geologists he found little need for those technical terms which are so apt to render science unintelligible to the general reader.

The manner of his introduction to the work of scientific investigation had its influence also on the quality of his work. As most of my audience are well aware, scientific investigation, or the endeavor to understand nature, consists of two parts, observation and theory. We open our eyes to the facts, or phenomena, as they are called, of nature, and make record of what we see, and then we endeavor to explain the phenomena by discovering how they have come to be. We observe and we theorize. But while observation and theory may logically be distinguished, in practice they must be intimately combined or the best results are not secured. There are, indeed, observers who take little cognizance of theory; but the best observers have theory constantly in mind, and through consideration of the relation of their facts to theory have their vision sharpened and their attention guided to those things which are most important. And there are theorists, too, who are indifferent to facts, soaring untrammeled in the realms of imagination and speculation. But the successful theorist tests every hypothesis by scrupulously comparing it with the phenomena to which it pertains, and modifies or rejects it when he discovers a discordance. It is by the observer who is also a theorist, and the theorist who is also an observer, that real progress is achieved.

As a teacher Orton derived from the literature of geology a body of theory which he complemented, so far as practicable, by personal observation of the rocks, minerals and fossils that lay within his reach. Thus he trained himself early to habits of observation, and in all his later work kept in close touch with the phenomena of nature. As an investigator he generalized freely and did not shrink from the propounding of theories, but all his theories were so broadly founded upon, and so faithfully verified by, the phenomena of observation that they came to the world as demonstrations which could not be gainsaid.

This far we have considered only Orton's work in pure science, but his work in applied science was of equal or greater importance, and it was in this field that his personality was most marked. I trust that you will bear with me in another digression at this point, for his life serves to illustrate certain peculiarities of the relation of man to science which are not always kept clearly in view.

It is a matter of common understanding that scientific knowledge, or knowledge of nature, is the foundation of the material progress of the race, but the method through which it serves this purpose is perhaps less broadly understood. Through research the body of 'natural knowledge' has been created and is constantly increased. This body of knowledge is a storehouse from which men may draw that which they find useful, and from which they do, in fact, make drafts at every stage of progress. But the store of knowledge grows quite independently of the drafts which are made upon it. The utility of the individual grains of knowledge is not foreseen, and their accumulation is always much faster than their utilization. So far as we may judge the future by the past, only a small portion of the garnered knowledge will ever find practical application, and thus, from the purely utilitarian standpoint, there is an immense waste of energy in the prosecution of research. This only illustrates the general fact that mankind is a part of nature, for in nature the ways of progress are ever wasteful. The acorn is nature's device to prevent the extermination of the oak, and an oak tree in its long lifetime produces a myriad of fertile acorns, but only one of these, on the average, escapes all the dangers of immaturity so as to develop a perfect tree; the others fail for lack of opportunity, and, so far as the continuance of the species is concerned, are wasted.

The gathering of this great store of natural knowledge, only part of which can serve the purposes of mankind, is called pure science. The utilization of such portion as may be found available constitutes applied science. If the practical ends of applied science constituted the only motive for labor in pure science, mankind would be appalled and discouraged by the enormity of the waste; but, fortunately for human progress, another motive exists in the love of knowledge for its own sake.

Every activity which is so often repeated as to become habitual affects mental constitution and may result in a corresponding sentiment, appetite or instinct, which in turn becomes a motive for the activity. Take, for example, the fundamental act of eating, which is essential to preservation of life and is common to all animals. There has been developed in connection with it a desire to eat, or appetite, which for most sentient beings is the actual motive, there being no perception of the relation of food to life. Men associated in communities find advantage in the classification and division of labor so that each shall perform some one function for others as well as for himself, being repaid through equivalent service by others. In order to exchange labor, or the products of labor, good faith is necessary, and coöperative living has accordingly developed the sentiment of honesty. Moreover, as industrial organization makes each individual continually work for others more than for himself, there is developed in him a sentiment impelling him to do for others, the sentiment of altruism. Again, the importance of social aggregation in the evolution of all phases of human culture has led to the creation of great nations, and national existence has engendered national sentiment, the sentiment of patriotism, but the masses actuated by patriotism as a motive have little conception of the value of aggregation as a factor in human development.

In a similar way scientific research as an essential to material progress has developed its own sentiment, the scientific sentiment, or the sentiment of acquiring knowledge for its own sake, and this is the motive of pure science. As honesty, altruism and patriotism are sometimes carried to absurd limits, so as even to oppose the ends they normally tend to promote, so the scientific sentiment is liable to perversion; and there are not wanting scientists so devoted to the acquisition of knowledge that they are impatient of its application, and look with disdain on other scientists who strive to discover its uses.

In the application of natural knowledge to human uses material gain is usually in sight, and this supplies a motive so distinct from the unselfish sentiment of science that the same individuals are rarely votaries of both pure and applied science. Taking an illustration from the branch with which I am most familiar, the mining engineers, occupied with the application of geologic knowledge and actuated primarily by the motive of material gain, are a distinct body of men from the geologists proper, occupied with the acquisition of geologic knowledge and actuated primarily by the scientific sentiment. There are, indeed, individuals who perform both functions, but as compared to the general body they are rare exceptions. Such an exception was Edward Orton, and he stands prominent among geologists as one actuated by altruistic motives not only in the acquisition of knowledge but in its application. Selecting, by preference, the geologic problems connected with the useful minerals stored in the strata of his State, he carried his work not merely to the inductions and theories of pure science but to practical utilitarian applications, and these were freely given to the community he served. Through official reports, through the columns of newspapers, and through personal conversation he imparted not only statistical information and general principles concerning the occurrence of ores and mineral fuels, but practical and timely advice as to their exploitation and conservation. Employed by the people, he labored for the people, and he gave them the bread for which they asked.

Orton's work in geology, so far as it is a matter of record, is largely connected with the survey of this State [Ohio.] For thirty years he was an officer of the State, and though not continuously engaged in its service nor always compensated in money for the work which he performed, it is believed that he devoted more time to its exploration and survey than any other geologist, and that his knowledge of the distribution, qualities and structures of its rocks was correspondingly intimate and comprehensive. His reports are so numerous and extensive and pertain to so wide a range of topics that I shall leave their enumeration to the biographer and bibliographer* and content myself with a simple outline.

An assistant geologist under the directorship of Professor Newberry he began work in 1869 in the southwest quarter of the State, called the Third District, and his labors were confined to this field for a number of years. Gradually, however, they were extended to coal fields farther east, and after the year 1882, when he practically assumed the functions of geologist in chief, the entire State was within his purview. He was also engaged for shorter periods in the investigation of oil and gas fields of Kentucky, Indiana and New York, and he made reports to the United States Geological Survey and to the Eleventh Census of the United States on various economic resources of Ohio and Indiana. His contributions to pure science were in part published by the Geological Society

* A list of scientific papers will appear in volume 11 of the Bulletin of the Geological Society of America.

of America and by various scientific journals.

Among his writings are many discussions of the character, sequence, extent and arrangement of the geologic formations underlying the State, and also of the deposits of drift which mantle the surface. He described in detail the geologic features of many counties, and he worked out and published the structure of most of the coal fields of the State, discussing not only the relations and extent of the seams, but their practical qualities. During the last two decades he gave great attention to the development of petroleum and natural gas, treating the scientific and practical aspects of the Ohio fields with a thoroughness which I believe to be without parallel. At various times he studied and wrote upon the building stones, limestones, iron ores, rock water, gypsum and clays of Ohio and other States, elucidating the geologic relations and usually pointing out also their economic bearings.

From the mass of material thus accessible I select for special mention a single contribution to pure and applied science, choosing the one with which his name is most frequently associated by brethren of the hammer at home and abroad. I refer to his study of the relation of gas, oil and brine in subterranean reservoirs. It was well known that the flow of oil from a well is often preceded or accompanied by the escape of gas; it was known that the life of an oil well was often terminated by the influx of water, and that this water, when derived from the same reservoir as the oil, was highly charged with mineral matter; it was known that the static pressure of natural gas in a well was usually the same for all wells of a group or district, and independent of the altitude of the opening; and partial explanations of these facts had been suggested by various students; but it remained for Orton to formulate a comprehensive theory explaining all the phenomena, and then, testing it by comparison with a series of measurements and other observations in the gas and oil fields of northern Ohio and Indiana, to place it on a sure and enduring basis. Like many another result of elaborate and successful investigation, his theory, when stated, appears so simple as to be almost axiomatic, and one is tempted to wonder why the common sense not only of geologists but of all concerned in the development of petroleum and natural gas had previously failed of its attainment; and yet nearly every part of it has been at one time or other the subject of attack and controversy.

Each stratum of porous rock containing a profitable store of oil and gas is sealed above by some impervious layer, so that fluids cannot escape upward, though it may communicate freely with the surface of the ground at a distant point, if only the communication involves an inverted siphon equivalent to the plumber's trap. Under these conditions the stratum constitutes a reservoir in which three fluids arrange themselves according to gravity; gas occupies the pores of the upper part, and is succeeded downward by oil, which in turn rests upon water. If the stratum reaches the surface of the ground at a place lying higher than the reservoir, the water supplied to it by rains exerts a pressure, in accordance with the familiar hydrostatic law, on the water in the reservoir, and this is communicated to the oil and gas. The gas is compressed until its elasticity counterpoises the weight of the column of water. If, now, a well is drilled so as to tap the reservoir at its highest point, gas rushes forth, being forced out by the pressure of the water. If a well reaches the reservoir in the zone occupied by oil, the oil is similarly forced upward, and may be discharged at the surface in case the pressure from the water is sufficient. If a boring taps the reservoir still lower, it reaches water, which is similarly forced upward and may flow at the surface. The water is always a brine, because, occupying a closed reservoir, it has no circulation and has been dissolving for ages the soluble minerals contained in the rocks; and it is thus contrasted with the potable waters of artesian wells, which contain comparatively little mineral matter, because they are parts of an underground circulation and their sojourn within the rocks is comparatively brief. An ordinary artesian water does not rise in wells everywhere to the same height, the pressure, or head, diminishing as distance increases from the source of supply; but the stagnant brine underlying a body of petroleum is everywhere subject to the same pressure, and will rise to the same height in any well to which it has access. This principle is intimately related to the pressure under which gas escapes from a well and its knowledge has been found of great practical value to the natural gas industry.

It follows from the theory, and it is also a matter of observation, that as the gas in a reservoir is drawn off through wells, the underlying oil and brine rise to take its place, and when the local store of gas has been exhausted, the wells either produce oil or are flooded by brine.

With the demonstration of this theory the earlier idea, that gas was forced outward merely by its own elasticity, and that it was generated in subterranean laboratories from fossil organic matter as rapidly as it escaped, was completely disproved. It became evident that the supply of gas in each reservoir was definitely limited; that if once exhausted, it could never be restored; that economy was required in the use of natural gas, as with any other resource; and that the folly which permitted it to escape freely to the atmosphere was also a crime. That such criminal and disastrous folly was actually perpetrated in most of the gas fields of northern Ohio and central Indiana was not the fault of Dr. Orton, who early sounded the note of warning, and strenuously combated the infatuation of the well owners.

Of the high esteem in which Orton was held by his colleagues in scientific labor you are already aware. The Geological Society of America, an organization including the leading geologists of the continent, chose him as its president, to serve for the year 1897; the American Association for the Advancement of Science, foremost in importance among American scientific bodies, called him to the chair of its geologic section in 1885, and bestowed its highest office in the last year of his life. Even in his own country he was not without honor.

G. K. GILBERT.

ADDRESS OF THE PRESIDENT BEFORE THE AMERICAN SOCIETY OF NATURALISTS. *

BEARING in mind that we have with us this evening representatives of all branches of natural science, it seems better that I should not attempt to give here a sketch of the progress of botany nor discuss the special problems which botanists are trying to solve. Botany is certainly progressing, but progress is not hastened by stopping too frequently to consider just how much progress has been made. As far as questions of botanical research are concerned the past year has not been marked by any startling discovery, but it has been rather a year of transition, and the work done may be expected to bear mature fruit later. The most striking feature of the past year in our own country has been the publication of a remarkably large number of treatises of an educational character in which the results of recent botanical work have been presented in a fresh and attractive form, but this is evidently not an occasion on which

* New Haven, December 28, 1899.

one should speak of their merits or point out their defects.

Instead of calling your attention to any special phase of botany I shall take the liberty of presenting a few considerations suggested by a comparison of the different methods of organization of universities and other scientific establishments in this country and in Europe. Such considerations, although they apply to all advanced studies and research, whether literary or scientific, are not to be considered beyond our province, for in more ways than may at first be supposed there is a community of learning, and any method or organization which genuinely promotes one form of knowledge tends to promote the study of other branches. I say genuinely because I do not believe that a system which professes to encourage the exclusive study of one or a few subjects will in the end be successful.

Although any organization may be better than no organization at all, there is a possibility of pushing organization to an extreme, and, by putting too many wheels into our educational clocks, produce a disastrous amount of friction. Organization should be carried so far that the knowledge which has been acquired slowly and laboriously from experience and research is systematized in such a way that the student may be able to learn all that is possible without loss of time, and the investigator, well informed as to what is already known, be able to take up the thread of the unknown and unravel it to the greatest advantage. When organization goes so far as to dictate just who should do certain things and to prescribe stereotyped ways of work, it is always disastrous. Since a good organization of the forces at our command is probably the most efficient means of securing steady progress in science, an examination of different modes of organization should prove instructive.

Without entering into the futile question of the relative inherent capacities of the scientific men of different European nations, it is safe to say that we should all agree that, in point of scientific organization, the German universities surpass all others. Probably most of my hearers have, at some time, pursued their studies in Europe, and, if they have attended German universities rather than those of other countries, it was because they were convinced that, however eminent individual professors might be elsewhere, Germany was the place where the university system would enable them to obtain most readily the results of modern science and to prepare themselves for investigation. Although we Americans are supposed to have a sufficiently high opinion of our own abilities and our own institutions, it is certainly true that we are willing to learn from other nations. A considerable portion of the Americans who have studied in Germany have on their return home a feeling that the German university system is better than our own and desire to introduce German methods, and it is not necessary to remind you of the great influence which such a feeling has had on our own universities. Our social and intellectual conditions, however, do not permit us to transform our universities completely into institutions like German universities, and there has grown up with us a system which is peculiarly American, of which the full significance has in an important respect often been overlooked.

When one asks how our universities differ from those in Germany and other European countries, the answer generally given is that students who enter foreign universities have had a more thorough preliminary training than our own; that the instructors, taken as a whole, have a more profound knowledge of their specialties; and that the equipment in the form of libraries, laboratories and museums is more complete than in this country. Were these the only respects in which our own universities differ from those of Germany, for instance, we might believe that the differences would disappear in the near future. Our preparatory schools, it is claimed, are improving; our university instructors are becoming better equipped for their special work, and, at least as far as natural history is concerned, our libraries and laboratories are numerous and some of them are hardly inferior, for all practical purposes, to those of the best European universities. Were the differences I have mentioned the only ones, we could say with truth that there is no radical difference between our universities and those of Germany, but merely a difference in the comparative development, which time would obliterate. There is, however, another fundamental difference, on which it seems to me too little stress has been laid, a difference which, as far as I can see, tends to become more marked or which, at least, shows no signs of diminution in the near future. I refer to the method of university government. Strange to say, although we are living in a republic, the whole tendency in our colleges and universities is towards a more autocratic form, while in Germany, on the other hand, it is of a more democratic character. In other words, excluding the purely political question of supporting or, at least, of not interfering with the administrative measures of the government in power, the instructing, the learned body, the faculty, has in Germany more power in regard to appointments and the general policy of the university, while with us, the greater power lies with the president and the boards known variously as corporations, trustees and overseers. The German universities have no president, in our sense, but the presiding officer is selected annually from the body of professors in rotation. Nor is there in the English universities any officer corresponding to our college, or university, president, the chancellorship being rather an honorary position than one of active duties.

The American president, on the other hand, is a true executive of such importance and intrusted with such power that the selection of a proper president is a vital question. If he is capable, the college is successful; if he is incapable, it quickly falls behind. The successful modern president is, furthermore, a very different person from the president of twenty-five or more years ago. Formerly the president was frequently a professor selected for his eminence as a scholar, due regard being paid to his orthodoxy. His position as president did not debar him from continuing to lecture as a professor. The modern president is less frequently selected from the body of professors, and, if so selected, he is chosen not so much on account of his eminence in science or literature as from his presumed ability as an administrator. In becoming president he almost of necessity relinquishes his position as a lecturer. He must above all things be a man of good business head whose previous experience has given him a knowledge of educational methods. It is the president rather than the faculty who, in the opinion of the public, shapes the policy of the American university, for, although, accepting the suggestions of the faculty, he may adopt them as his own policy, he is not under the necessity of doing so, and the skillful president is usually successful in inducing the faculty to recommend the policy which he thinks advisable.

The preponderating influence of the president and financial board as compared with that of the faculty or board of instructors seems to me to be the most striking feature in our American system as compared with the European university system. The system has gradually developed with us from the time when one person combined the functions of professor and presiding officer. During the last 15 or 20 years the relative importance of the president has been more marked, owing to the fact that by the transformation of the older colleges into universities the amount of administrative work has been greatly increased, and with it has come the increasing necessity of depending more and more on the intelligence and activity of a single mind as supervisor and administrator. Furthermore, the remarkable increase in the number of colleges and universities, none of them with sufficient endowment to provide the elaborate equipment and large body of instructors required in a modern university, has brought about a competition between different institutions, each struggling to outdo the others, so that the college president has been forced to become a 'hustler,' to borrow an expression from the business world, and he is obliged to see that his own institution is not outdone by others in the scramble for private and public money to carry on establishments requiring additional sums for proper endowment. Whether we like it or not, I think it will be admitted that what I have described as peculiarly the American system of university organization is one which we must accept as unavoidable in this country, and there is no probability that the system will be changed essentially in a short time. That being the case, it is our duty to adapt ourselves to it and make the best possible use of it, not expecting that we shall be able to copy closely the systems of other countries except in certain details, which, however, are important.

The great charm of the German university hitherto has been what has been described as the intellectual atmosphere, the prevailing desire of pursuing learning and investigation for their own sake, which, however, does not unfit the Germans for the successful application of science in industrial and practical fields. We miss in our own universities this universal desire for investigation, which is with us confined to a certain number of persons who are very enthusiastic, to be sure, but are in most cases obliged to justify themselves in the eyes of those who do not understand the value of investigation.

Fashion and the natural tendency to imitate others has, however, done very much for us in recent years in aid of investigation, for, while it may be next to impossible to induce the governing board of a university to spend money on investigation for its own sake, it is a comparatively easy matter to convince them that they must make provision for original work because some other institution has done so and is thereby attracting public attention. If original research can be used as a means for advertising a university, there is no doubt that it will be encouraged, and, fortunately, as it turns out, it is a very good advertisement, even better than victories in athletics. The really successful American universities are those in which the most original work is done. The trouble is that if one looks upon research mainly as an advertising medium, one is apt to demand quantity rather than quality, and to regard the number of papers published annually as the standard of scientific activity.

The pursuit of science for its own sake which characterizes the German universities is one of the results of their form of organization. The faculty, the learned body, shape their own policy more than is the case with us, and they recognize the intrinsic value of research. With us it is necessary, through the president, to convince the corporation and trustees of its value before much can be done, and they, being for the greater part business men or professional men, rather than scholars, are apt to consider that research is valuable only in so far as it is what they call practical. In this view they undoubtedly represent the American public, and it is from the public that the money must be obtained for carrying on research, either directly from private individuals in the case of endowed universities, or indirectly through the legislatures as representing the public in the case of the State universities. The misfortune is that the word practical means nothing in particular, for even abstract science sooner or later has a practical application, and it often happens that what is supposed to be very practical is merely empiricism which a thorough theoretical study would show to be false.

It would be unjust not to admit that there is something to be said on the side of governing boards in the attitude which they take towards research. Research is expensive, and when the professors ask that it be encouraged that means something more than sympathetic words. It means money or relief from an excessive amount of teaching, which is the same thing as money, for some one must be paid to do the teaching. It can hardly be supposed that the governing boards are really opposed to research, although they at times overrate the value of formal instruction as compared with research. They feel that they have no money to spend, which is, unfortunately, often true, and, on the other hand, they do not understand the absorbing nature of research and the necessity for giving one's close attention to it. So long as research is subordinated to other work it cannot accomplish the best results, and any occupation, whether it be excessive routine work in the way of lectures or laboratory instruction, or whether it be the enforced necessity of going about and talking to private individuals or members of legislatures for the purpose of obtaining money for a proper equipment, stands in the way of, if it does not entirely check, research. In Germany the professors are able to pursue their original work without feeling that one of their functions is the raising of money for carrying on the work. Unfortunately, in most of our scientific establishments, in speaking of the professors, the double-headed question is not unfrequently asked: What work are they doing and how much money have they raised for the support of their laboratories? For the credit of American science, it is to be hoped that this question will soon be reduced to the simple inquiry as to the work done.

Hitherto I have spoken of American colleges and universities somewhat indiscriminately, since it is not possible to distinguish between them, some colleges not differing essentially from universities, while some so-called universities are not universities in any sense. By whatever name they are called my remarks apply to institutions in which advanced instruction is given, looking ultimately to original research by specially qualified students and by the instructors, and in the same class should be included the better scientific schools, for, although it is hardly proper strictly to compare their organization with that of a German university, many of the anomalous conditions found in our universities and colleges are found also in our scientific schools. I have assumed that all such institutions have the double function of teaching and investigation, a dogmatic view perhaps, but one with which I presume most, if not all, of those present this evening are in sympathy, although there are people, especially some who think that they are very practical, who hold a different opinion.

We believe that the two functions must be combined in a university because we know from experience that, in the cases where instruction is considered to be the sole function, stagnation, not progress, is the result. On the other hand, if research were the sole function of a university, it would be difficult to see where else those desiring to become investigators could be properly trained. The real question is as to the amount of instruction.

It has been the custom in comparing our universities with those of Germany to lament the absence of uniform standards of admission requirements and of qualifications for higher degrees in this country. If by that is meant that it is to be regretted that our standards are not higher, the lamentation is justified. But if, as some think, what we need is a uniform standard in these respects, to be enforced by agreement of the different universities or initiated by the establishment of a national university, I, for one, am thankful that we have no such uniformity. The present uniformity in Germany is the result of an old civilization, and the prevalence of similar educational and intellectual conditions for many years. In the course of time our educational conditions will become more and more uniform and we may have, perhaps, uniform standards of admission and graduation, but, if so, they will be the results of a natural development, not of prescription. So long as the social and political conditions of the different parts of our country differ as they do, real uniformity in university standards is out of the question. Even in sections of limited area the attempts at enforcing uniformity among the different colleges have at times shown the ease with which rules can be kept in theory and yet broken in practice.

The possibility of establishing a genuine national university superior to all others in equipment and authority seems to most of those interested in educational matters to be remote, but, were it possible to have such a university, one could hardly imagine a greater misfortune to learning in America. One need only glance at the condition of things in Germany and France to recognize the benumbing effect of concentrating in one place, especially if it be the political capital, the greater portion of the scientific establishments. The wide-spread intellectual activity of Germany is, I think, mainly due to the existence in times past of many scattered universities, some better than others, no one, however, superior to all the rest, but all centers of learning, generous rivals in the promotion of knowledge. Whether under imperial Germany the concentration of resources on fewer universities, with a tendency to still greater concentration hereafter, may not have an unfavorable effect on the nation in the long run, is a question which the future must answer. That the concentration of scientific work and workers in Paris has had an injurious effect on France is evident to the French themselves, and they have in recent years made efforts to strengthen the universities in other parts of France. Our country is so large and so varied in population and occupation that we need many independent centers of learning and numerous universities, zealous in promoting knowledge, but not subordinated to a national university, either directly or indirectly, by the expenditure of national funds on a single institution. Whether such universities should be privately endowed or supported by the States is a question to be settled in each case by the locality and tradition.

If it is true that the promotion of science and learning in a country like ours is best accomplished by the existence of numerous independent universities, there is still a large field of research on which government funds may be legitimately spent. The principle that what can be well done by privately endowed universities, or by those supported by the States, had better be left to them rather than be undertaken by the national government, seems to me to be a sound one and to be in accord with the spirit in which our government was founded. Centralization in science, as in government, may be necessary at times, but is to be avoided when possible. There must, however, always be questions affecting the national welfare which it is undoubtedly the function of the general government to investigate. The study of contagious diseases of man and animals, involving as it does questions of quarantine and other sanitary regulations, which may affect any or all the States, and the study of plant diseases, however caused, and the means of prevention, are good instances of the kind of work which should be undertaken by the national government, for they are of such eminently practical nature and so general in their application that it is important that the government should have constantly in its service experts capable of studying them and of giving at short notice information that may be needed. The theoretical aspects of the subjects mentioned and the study of certain special cases may profitably be undertaken by private or State institutions, but the resources and authority of the general government are needed for the obtaining and spreading of information and the enforcement of preventive or remedial measures. It is an important duty of our universities and scientific schools to train up a body of young men capable of entering the different governmental bureaus as scientific experts, that is to say in the lower grades, for it is not supposed that without a more or less lengthy active service in the bureaus themselves one would be prepared to fill the higher positions. In Germany there seems to be no difficulty in finding among the graduates of universities and technical schools well-trained young men for the scientific establishments of the government. If things are not in so satisfactory a state here it is due, in part, to the very rapid enlargement of the scope of government work in recent years, and there is no reason to suppose that before long the supply of well-trained young men will not equal the demand.

In my remarks this evening I have felt free to state what, to the best of my knowledge, seems to be the condition of our scientific organization, especially in our universities; but in what I have said I have endeavored merely to describe the situation viewed generally, and, if I have taken this occasion to refer to some points in which our system might be improved, I have done so without reference, either expressed or implied, to any institution or locality, but because I cannot help feeling that a plain statement of certain difficulties from which many, if not most of us, suffer is the first step to be taken if we are to expect improvement. I have described the older German universities as generous rivals in the promotion of knowledge. From conditions beyond our control we are at present in a condition of unrest and feverish ambition, each university striving, on insufficient means, to do all that any other university is doing. When shall we become cool-headed enough to do well and thoroughly what our means permit, and wait patiently for the time when we can expand farther without too great tension or attenuation of the resources now at our command?

HARVARD UNIVERSITY.

INHIBITING ACTION OF OXIDASE UPON DIASTASE.

IN the disease of the tobacco leaf known as Calico, or Mosaic, the lighter-colored areas are found to contain more starch in the form of granules than do the green areas of the same leaf. This is very peculiar, inasmuch as the chloroplasts of the light-colored areas are evidently in an unhealthy condition.

In an article published in the *Centralblatt für Bakteriologie*, II Abt. Bd. V., No. 22, I have pointed out the fact that these light-colored cells exhibit much more oxidizing activity than do the green cells of the same leaf. The light-colored areas were found to correspond with the light-colored patches produced by insect punctures, certain fungi, and especially in that group of diseases known as variegation or albinism.

All these cases show a greater amount of oxidizing enzymes (oxidases as well as peroxidases) in the light-colored tissues. Mainly upon this evidence I was obliged in the article mentioned to differ from most other writers on the disease in question, in calling the lighter-colored tissues diseased, and the deep green patches, especially along the veins, healthy. It is true that much tobacco is apparently normally as light colored as the light-colored areas in the diseased leaf, but, on the other hand, there is quite as much which is normally as green all over as the green areas in many of the diseased leaves. It is true that some of the green patches, especially where the light-colored areas are unusually light, are abnormally green. A study of the histology of the diseased leaves has now revealed a histological difference which makes it very clear that the light-colored areas are not normal, and this difference consists in the fact that in badly diseased plants the palisade parenchyma of the light-colored areas is not developed at all. All the tissue between the upper and the lower epidermis consists of a spongy or respiratory parenchyma rather more closely packed than normal. In moderately diseased plants the palisade parenchyma of the light area is greatly modified. Normally the palisade parenchyma cells of a healthy plant are from four to six times as long as broad. In a moderately diseased plant, however, the cells are nearly as broad as they are long, or at most not more than twice as long as broad. As a rule, the modified cells of the leaf pass abruptly into the normal cells of the green area. In a badly diseased leaf simply looking across the surface with the naked eye shows depressions where the light areas occur, or where the leaf is mostly diseased the dark green patches are raised above the general surface.

The cells of the diseased area also translocate their starch with difficulty, the cells often becoming completely gorged with this material. The examination of the diseased spots early in the morning shows only a small decrease in the starch content of the cells from that present the previous afternoon, while the green, healthy tissues either contain no starch or contain only traces of it. It was thought that possibly the increase of oxidizing enzyme might either inhibit the production of diastase by the cell or inhibit the action of diastase upon starch. In order to settle this point strong solutions of tobacco oxidase were prepared, and after heating some of the solution to the boiling point, thus killing the oxidase, comparisons were made by adding 10 milligrams of taka diastase in solution to each of the tubes of juice to be tested. Equal quantities of freshly prepared potato starch paste were then added to each tube and the tubes kept at 45 degrees Cent. It was found that in the solution without oxidase the starch was completely converted into sugar in thirty minutes, while the solutions in which the oxidase was active only carried the change of the starch to the erythrodextrin stage. The action of the diastase of malt added in solution in the same quantity was somewhat less rapid than that of taka diastase, but the relative effects were exactly the same : the presence of the oxidase in the solution had a marked inhibitory action upon the activity of the diastase.

In these tests the proportion of diastase to oxidase was much greater than occurs even in the diseased cells, so it is likely that the inhibitory action of the oxidase in the cells is much greater than that shown in the tests outside of the cells.

It would seem a warrantable conclusion, therefore, that the tardiness in the translocation of starch in the diseased area is to be explained by the abnormal activity of the oxidizing enzymes of these cells, and that the mode of this action is by retarding or weakening the activity of the translocation diastase. This would also help to explain the slower growth of the diseased cells.

*THE MEXICAN HALL OF THE AMERICAN MUSEUM OF NATURAL HISTORY.**

When the Europeans first set foot in Mexico, they were met by a numerous people who had become settled into nations, and had developed a civilization which was astounding and incomprehensible to the conquering adventurers. The antiquity of this American civilization was so great, and it was so widely spread over Mexico and Central America, that there still remains a vast accumulation of materials exemplifying the daily life of the people. Hundreds of temples and other large and elaborate structures and sculptures in stone, which were connected with the ceremonials of an all-pervading religion fostered and maintained by priests and rulers, stand as monuments of this ancient civilization.

Several distinct phases of this culture resulted from modifications by different tribes with distinct languages and customs. In Mexico proper the most powerful nation was that of the Nahuas, commonly known as the Aztecs. Their principal seat was in the Valley of Mexico, but by migrations and conquests they left their imprint in various parts of Mexico and Central America. The other prominent cultures of this ancient time in Mexico are attributed to the Tarascans in the States of Michoacan and Jalisco, the Zapotecans and the Mixtecans in the State of Oaxaca, and the Totonacans in the State of Vera Cruz. The great southern development, in many ways the highest phase of this American civilization, is attributed to the Mayas. It extended from the State of Chiapas on the north, through Yucatan and Guatemala, to northern Honduras, where in the Copan Valley it probably reached its highest development.

From the time of the conquest by Cortes this ancient civilization on the American Continent has been a wonder and a mystery. Some of the Spanish priests and native writers following the conquest left accounts of the people and their customs, from which the student of to-day is obtaining important information; but it is only during the present century that serious research has been directed to the study of this remarkable phase of American archæology. The publication, by Stephens in 1841, of the volumes containing illustrations by Catherwood of the ruins in Chiapas, Yucatan and Central America, first aroused attention among English-speaking peoples to the ruins of these ancient cities of America with their strange sculptures. From that time this interest has been increasing, and during the last decade systematic exploration and research have led to many important discoveries, the beginnings of definite knowledge concerning the origin and development of this past American civilization.

It was in furtherance of this research that the American Museum secured from the Government of Mexico the right to explore the ancient ruins in that country. It was for this object that Mr. Lorillard provided the means for Charnay's expedition to Yucatan and other parts of Mexico. It was this incentive that led Mr. Thompson to take up his abode in Yucatan, and that induced Dr. and Mrs. Le Plongeon to pass years of arduous labor in that country. For this purpose the Duke of Loubat sent

* Opened on December 12, 1899.

Dr. Seler on a special expedition to Mexico and Central America; and to this end Mr. Maudslay, of England, has devoted much of his time and private means. For the same purpose Messrs. Bowditch, Salisbury and others have for several years given their generous support to the Peabody Museum of Harvard University, that explorations might be carried on in Yucatan, Guatemala and Honduras.

All this research has made it possible to secure such an exhibit as is now installed in the Mexican Hall of the American Museum of Natural History; but it is due to the intelligent interest and liberality of the Duke of Loubat that the Museum has been able to bring together this large and important collection, which is soon to be exhibited for the instruction of the public.

The originals of the great sculptures in stone, of which facsimile casts are here presented, are, with the exception of a few specimens in other museums, still buried in tropical jungles or amid the ruins of ancient temples. The general labels on each of the larger specimens, and the illustrated labels in the frames near them, give information relating to each of these sculptures (known as monoliths, stelæ, idols and altars) from the prehistoric ruins of Quirigua in Guatemala and of Copan in Honduras. These are all monuments of the Maya culture, and on most of them will be seen groups or columns of hieroglyphs, the deciphering of which is one of the most important researches in American archæology. The sculptures at the farther part of the hall are from Mexico, and belong mostly to the Nahuatl culture. The dark color of the casts shows that the originals are of a different kind of stone from that used in Quirigua and Copan.

On entering the hall, the most conspicuous object on the left is the so-called 'Great Turtle of Quirigua.' To the right is a large 'idol' known as the 'Dwarf,' because it is the smallest of the stelæ standing amid the ruins of Quirigua. A cast of the largest of these monoliths, standing twenty-five feet above ground, is too high for this hall. It is exhibited in the hall below, where from the gallery a study can be made of the upper portions of the sculptures.

On the right of the hall is a restoration of the sanctuary of the 'Temple of the Cross,' showing the position of the bas-relief known as the 'Tablet of the Cross,' with the officiating priests and the hieroglyphic inscription. In a frame on the side of this reconstruction is an illustrated label explanatory of this temple at Palenque. In the table-case near by are several pieces showing hieroglyphics and figures made in stucco, which was widely used. The great 'Calendar Stone,' the most remarkable of Mexican sculptures, is shown on the south wall. On the walls and screens on the north side of the hall are many fine bas-reliefs from ruins in Guatemala, Honduras, Palenque and Yucatan. Over the northern case at the east end of the hall is a group of slabs from Palenque, upon which are many columns of hieroglyphs. Over the adjoining case, and on the south wall near by, are casts of slabs from the ruins of Chichen Itza in Yucatan. Here are also the sculptured stone posts of a doorway upon which rests a carved wooden lintel. To the right of this is shown the sculptured wall of a portion of a room in a temple at Chichen Itza, on which are many human figures and a feathered serpent. There is evidence that this and many of the other sculptures were formerly painted in several colors, of which red, yellow and blue predominated. The statue of Chac-Mool, found by Dr. and Mrs. Le Plongeon at Chichen Itza, is an instance where the colors were still preserved. The cast of this reclining statue was colored by Mrs. Le Plongeon in exact copy of the original when found.

In case A are the Tarascan terra-cotta figures and stone sculptures secured by the Lumholtz expedition.

In case B, on the east end of the hall, are original sculptures in stone from Copan and Yucatan.

In case N is a collection, also from the Lumholtz expedition of pottery from the ruins of Casas Grandes, illustrating a culture approaching that of the ancient Pueblo people of Arizona and New Mexico.

In three other cases at this end of the hall, and several cases at the opposite end, are various collections, including jadeite ornaments, copper implements and ornaments, carved stone yokes, a large terra-cotta human figure, and pottery vessels of many forms, all illustrative of the culture of several of the ancient Mexican peoples.

Cases C and D contain the collections made by Dr. Seler in Mexico and Guatemala, and presented by the Duke of Loubat. In another case are terra-cotta figures of great value found over a tomb in a mound at Xoxo by Mr. Saville of the Museum expedition. A cast of the inscribed stone lintel of the door, and many vessels found with skeletons in this tomb, are most interesting objects.

The ancient Mexicans and Mayas had many manuscripts or codices consisting of picture-writing and of hieroglyphs. These were on prepared deer-skin or on native paper made of maguey fiber and coated with a kind of white cement. Several of these codices were sent to Europe soon after the Conquest, and others have since been found. They are of the utmost importance; but, being few in number and widely scattered, they were of little use until reproduced in facsimile, so that every student could have access to them for comparative study. In the two cases in the center of the hall, and in the frame over them, are a number of copies of these important records. For these the Museum is indebted to the Duke of Loubat, at whose personal expense several of these manuscripts have been reproduced in facsimile.

There is thus brought together in this Mexican Hall of the Museum the most important collection in existence for the study of the ancient civilization of Mexico and Central America.

HARVARD UNIVERSITY.

CORRESPONDENCE RELATING TO COLLECTIONS OF VERTEBRATE FOSSILS MADE BY THE LATE PROFESSOR O. C. MARSH.

THE following copies of letters have been sent to the Editor of SCIENCE by Hon. Charles D. Walcott, Director of the United States Geological Survey.

DEPARTMENT OF THE INTERIOR,
UNITED STATES GEOLOGICAL SURVEY,
WASHINGTON, D. C., May 5, 1891.

THE DIRECTOR,
U. S. GEOLOGICAL SURVEY,
WASHINGTON, D. C.

SIR:

* * * * * * *

The large collections of vertebrate remains in the charge of Professor O. C. Marsh, at New Haven, Connecticut, are kept in the fire-proof Peabody Museum building, and in a large storage shed adjoining. The method of recording is somewhat different from the other collections, but it is very thorough and complete.

In the field where the specimens are collected a label is placed inside of each box as it is packed. On this U. S. Geological Survey is printed in bold letters. On the outside of the box U. S. Geological Survey is plainly marked before the boxes are shipped. When received at Professor Marsh's laboratory in New Haven, a record is made of each box received and to each an entry number is assigned. This number is at once recorded on the box and, when the box is opened, on the label and on each and every specimen contained in the box with an oil paint. When it is necessary to remove a number in working out specimens from the matrix, the number is copied on some other portion of the rock or directly on the fossil before it is removed from the other portion. This number is the record of locality, stratigraphic position, and history of discovery; additional information is added from time to time under the number in the record book. This includes the identification of the genus and species and any data that may be of importance. The removing of the number from any specimen at once deprives it largely of scientific value, and it is to the interest of every one working on the collection to have it kept intact. When the final work is done and the specimen is identified, labeled with its name and ready for exhibition, it then receives a catalogue number. The old number, however, still follows it in the record of the latter.

The record of the entry number is kept in duplicate and Professor Marsh is now preparing another duplicate set to be filed with the Geological Survey. This record will show the number of boxes of specimens received, from 1882 to 1891. The laboratories and storage rooms provided by the Yale University Museum represent a floor space of over 9000 square feet, for which the Geological Survey does not pay rent. In addition to the collection at New Haven, there are seventy boxes of vertebrate fossils stored in the Armory building in Washington, and a collection is now being prepared for exhibition in the United States National Museum.

* * * * * * *

Respectfully yours,

(Signed) Chas. D. Walcott,
Paleontologist.

Department of the Interior,
United States Geological Survey,

December 8, 1899.

Professor S. P. Langley,
Secretary, Smithsonian Institution,
Washington, D. C.

Dear Sir: I have the honor to state that all the vertebrate collections of the late Professor O. C. Marsh, belonging to the Government, have been shipped from New Haven, Conn., and are now transferred to the custody of the U. S. National Museum, subject only to the use of such material as may be necessary for study and illustration in the completion of the monographs that were in course of preparation by Professor Marsh at the time of his death.

From a statement submitted by Mr. F. A. Lucas, who had charge of the packing of the collections, it appears that there were 1200 trays (20–26 inches) of specimens, 200 unopened boxes as received from the field, 30 blocks and 90 prepared specimens. To ship this material required 592 boxes, forming five car loads, having an aggregate weight of 160,000 pounds. To this there should be added two car loads containing 211 boxes received from Professor Marsh on deposit in 1891 and 1898.

The actual number of specimens represented in this collection cannot be stated. They range in size from minute teeth of fossil mammals to individual specimens weighing from 500 to 2000 pounds each. The collections are rich in large Dinosauria, especially in examples of *Triceratops* and *Stegosaurus*, while the series of Titanotherium skulls is one of the best, if not the best, in existence. It contains 50 or more complete examples cleaned, and a number in the rough, besides many hundred bones.

Among the specimens transferred are the types of 40 or more species, including Dinosaurs and Jurassic, Cretaceous and Tertiary mammals. Among the types are the following:

DINOSAURS.	JURASSIC MAMMALS.
Diplodocus longus.	*Paurodon valens.*
Labrosaurus ferox.	*Manacodon rarus.*
Camptosaurus nanus.	*Enneodon crassus.*
Triceratops sulcatus.	*Enneodon affinis.*
Triecratops californis.	*Laodon venustus.*
Triceratops obtusa.	CRETACEOUS MAMMALS.
Pleorocœlus nanus.	*Priconodon crassus.*
Ceratosaurus nasicornis.	*Cimolodon agilis.*
Ceratops montanus.	*Telacodon præstans.*
Ceratops alticornis.	*Oracodon cenulus.*
CROCODILES.	*Allacodon pumilis.*
Rhytidodon rostratus.	*Batodon tenuis.*
SNAKES.	*Allacodon fortis.*
Coniophis precedens.	

I requested Mr. Lucas to make an appraisement of the value of the specimens. He states that this is a very difficult thing to do, but that many of the specimens could not be replaced, and some specimens, like the skulls of the *Triceratops*, should be worth at least $5,000 each, while crania of *Titanotherium* are worth from $50 to $250 each, according to perfection, and that an estimate of the value of the entire collection will be upwards of $150,000. This is, of course, tentative, as some of the material has not been worked out at all, and some not removed from the boxes in which it was shipped from the field.

It is to be recalled that these collections were made by Professor Marsh during his connection with the Geological Survey, from 1882 to 1892 inclusive; that prior to his connection with the Survey he made large collections, including the toothed birds, the *Dinocerata*, *Brontosaurus*, many Dinosaurs, and the best *Titanotherium* yet discovered. He also purchased numerous collections after the stopping of allotments for his work in 1892. These collections were transferred to Yale University some time prior to his death.

As there has been considerable comment in relation to this matter, I send you a copy of a report on the examination of the collections under Professor Marsh's charge, made by me to the Director of the Geological Survey, in 1892.

I twice visited New Haven while the collections were being packed, and am fully convinced that all material belonging to the Government has been transferred to Washington. Mr. Lucas reports that the Trustees of the Peabody Museum in New Haven gave him every facility for packing the collections, and that the records were so complete that no difficulties arose in determining those specimens which belonged to the Government and those which were the property of the Peabody Museum.

The transfer of these great collections to Washington without the loss of any material, either through imperfect recording or through misunderstanding as to the ownership of specimens, reflects the greatest credit on the business-like methods and the integrity of Professor Marsh. The addition of the material to the National Museum places it in the front rank among museums in its collection of vertebrate fossils. It is necessary that some gaps in the collections be filled, and I sincerely trust it will be possible for the Museum to do this at an early date.

Yours respectfully,

(Signed) CHAS. D. WALCOTT,
Director.

INCLOSURE.

SMITHSONIAN INSTITUTION,
December 22, 1899.

DEAR SIR: I take great pleasure in acknowledging the receipt of your letter of the eighth instant, advising me that you have transferred to the National Museum all the vertebrate fossils collected by the late Professor O. C. Marsh belonging to the United States Government, subject only to the condition that such material as is required may be used for study and illustration in completing the monographs which were in preparation by Professor Marsh at the time of his death.

The addition of this immense collection of most important American fossil remains to the treasures already assembled in the National Museum will, I am sure, afford the greatest satisfaction to all workers in the field of paleontology both at home and abroad, and you will permit me to add a personal word in appreciation of your untiring efforts to facilitate in every way possible the great task connected with the removal of the collection from New Haven to Washington.

During the coming year I expect to have two preparators engaged in working out of the matrix specimens still uncleaned, and confidently hope that it may be possible in a few years to have the entire collection made available for study and a selected series for public exhibition. From this latter series the public will be able to form a correct idea as to the number, variety and great size of these wonderful extinct creatures of the western country, and will undoubtedly be impressed with the extent and importance of the work of the paleontological divisions of the Geological Survey and the marvelous industry and intelligence displayed by Professor Marsh in bringing together this great collection.

Yours respectfully,

(Signed) S. P. Langley,

Secretary.

The Honorable Charles D. Walcott,
Director United States Geological Survey,
Washington, D. C.

SCIENTIFIC BOOKS.

On the Building and Ornamental Stones of Wisconsin. By E. R. Buckley, Ph.D. Bull. No. IV. Economic Series No. 2. Wisconsin Geological and Natural History Survey. 1898.

The first attempt at a systematic investigation of the building stones of the United States was undertaken by Dr. G. W. Hawes under the auspices of the 10th Census. With the untimely death of Dr. Hawes the completion of the work fell into the hands of others, none of whom were experienced and some of whom had received no training such as should fit them for special investigations of this nature. Under such conditions it is not strange that the printed volume* should have been somewhat disappointing. Nevertheless it furnished a beginning and at least served to show what was not known on the subject.

This was followed in 1887 by Merrill's Handbook of the Collections of Building and Ornamental Stones in the United States National Museum,† which was based upon the Census Collections; and later by Stones for Building and Decoration (Wiley & Sons, New York), the first edition of which appeared in 1891 and the last in 1897. The above constitute the only comprehensive systematic treatises compiled with reference to the United States that have thus far appeared.

Several excellent special and local reports have, however, been made, among which should be mentioned Winchell's report on the building stone of Minnesota,‡ and the reports of Smock on those of New York; § Williams on the Syenites of Arkansas; || Hopkins on the Marbles of Arkansas, ¶ the Brownstones of Pennsylvania, ** and the Carboniferous Sandstones of Western Indiana; †† Macallie on the Marbles of Georgia; ‡‡ H. F. Bain on the

Stones of Iowa;* and lastly that of Mathews and Merrill on those of Maryland.†

The volume noted at the head of this article, bearing the date 1898 but seemingly not issued till the latter part of 1899, is the latest and most pretentious of them all, with the exception of that of the 10th Census, comprising some 566 pages with 49 full-page plates and four figures in the text. The plates include a colored geological map of the State and seven others in which the natural colors and textures of the stone are approximately reproduced by lithographic processes, the remainder being half-tone reproductions of quarry views and stone structures. The work is divided into three parts: (1) Demand, Uses and Properties of Building and Ornamental Stones; (2) Geological History of Wisconsin and Description of Areas and Quarries, and (3) Appendix, On The Composition and Kind of Stones.

The chief interest and value of the work center in part II. (pp. 75–357 inclusive), since the only information heretofore available on these points has been that given in the 10th Census report above referred to, and Merrill's Stones for Building and Decoration. The work has apparently been well and thoroughly done. By far the most interesting stones described, and the ones which on account of color may hope to find a market beyond the State limits, are the Montello, Waupaca, Waushara and Wausau granites, and the Berlin rhyolites. The brown sandstones of the Lake Superior region should, in the Middle and Western States, fill the place of the red brown Triassic stones in the Eastern. In nearly every instance samples of the stone described have been submitted to laboratory tests and their crushing strength, absorptive and general weathering properties ascertained, so far as is possible by these methods. It is a trifle discouraging to note that it was considered necessary to go to the expense and trouble of making over 100 tests of crushing strength on rocks which even a casual inspection would have shown to be sufficiently strong for all practical purposes. Concerning the value of such tests the present writer has expressed himself elsewhere.

* 8th Ann. Rep. Geol. Survey of Iowa, 1898.

† Vol. II., Rep. State Geol. Survey, 1899, pp. 241.

If one were disposed to be critical he might call attention to the carelessness manifested in some of the very few references given, and to the tendency to ignore the work of others, Professor A. D. Conover's paper of fifteen quarto pages in the report of the 10th Census, not even being mentioned. There is, further, a non-convincing air of freshness in the explanation put forward on p. 383, to account for the unfavorable action of freezing temperatures on newly quarried material.

Colored illustrations add to the attractiveness of the book, but are to some extent misleading, giving a perfection of surface and brightness of color, which the materials themselves do not possess. This is particularly the case with the red and pink granites. Plate 34 of the Lake Superior sandstone is also disappointing, as, indeed, is plate 45 of a similar subject in the 10th Census report, and plate 27 in that of the Maryland Survey. The attempt is instructive, as showing the relative merits of lithographic reproductions from colored drawings, as compared with the tricolor photographic process used in the Maryland report, the advantage however, being wholly with the latter.

Very poor taste has been shown in the arrangement of the views of quarries and structures in the half-tone plates, and particularly those numbered 4, 17, 24, 42 and 47. A picture which does not illustrate some definite feature is out of place in a work of this nature, and, if of value, it should be so oriented on the page as to be easy of reference. The fad for placing the several views on one page at varying angles with one another is not readily excusable, and in this particular case the effect is very inartistic as well.

There is much to be commended in the work, but it is not too much to say that it would be more useful if of half the size. The amount of paper involved is out of all proportion to the information contained therein.

GEORGE P. MERRILL.

Untersuchungen über die Vermehrung der Laubmoose durch Brutorgane und Stecklinge. By DR. CARL CORRENS, a. ö. Professor der Botanik in Tübingen. Jena, Gustav Fischer. 1899. Pp. xxiv + 472. 187 figs. Price, 15 M.

This extensive and very detailed work brings together a large number of observations on the vegetative reproduction of the true mosses by means of cuttings and of gemmæ, by which are meant those structures which serve, like the spores, to disseminate the plant over more or less extended distances. Interesting matters of biological interest are suggested to the mind by the analogies existing between these organs and seeds, but these will be referred to later on in the review.

The text is divided into two parts. A first or special part consists of a descriptive treatment of gemmæ and cuttings and of their behavior, arranged along taxonomic lines. The general part which follows treats of the morphological and anatomical structure of the organs under consideration, of their germination and of the conditions necessary for their occurrence and growth.

The large number of observations brought together in the special part prevent any adequate presentation in the limits of a review, so that it is possible only to point out that the great variety of asexual reproductive bodies which are found in the mosses may be reduced to a few types, viz.: the stem, leaf and protonema types. The stem type is found in those plants in which the stem is transversely breakable at intervals throughout its length, or merely at its base or apex. In this type the leaves may be reduced, resulting in bulbil formation, or the stem, to form brood-buds.

The leaf type occurs in forms in which the leaf is broken off as a whole and germinates, or is separable into fragments, each acting similarly.

True brood-bodies, so called by the author, arise only from the protonema in the wide sense, including that produced from the stem (rhizoids) and the chloronema.

The facts in this part which will interest especially, perhaps, the general botanist, are those relating to the methods by which these brood-organs are separated from the parent plant. This separation is accomplished either by the tearing of certains cells (rhexolytic) or by a splitting apart of cells by the behavior of the inner lamella (schizolytic). The rhexolytic process may be provided for by a special zone of cells or by a single cell, according to the complexity of the structure. The cell appointed for the sacrifice is called by Professor Correns a 'tmema' a term which constitutes a very picturesque addition to botanical terminology, the more so when one contemplates its compounds 'dolichotmema,' 'brachytmema' and the hybrid 'strecktmema.'

In the special part are first discussed the morphology and phylogeny of the brood-organs. Here the author advances the notion that the aërial part of the moss plant (*i. e.*, the stem and leaf) is phylogenetically older than the protonema and that it results from a reduction of the moss stem, though not, says the author, in the sense of Sachs and others, according to whom the oblique position of the transverse walls of the protonema is an indication that its terminal cell is the homologue of the apical cell of the moss stem, an explanation which, it will be conceded quite generally, is forced. According to the author's view, the forms such as *Ephemerum* and *Buxbaumia* are reduced and not primitive as to their shoot characters. This statement is probably correct in itself with regard to *Buxbaumia*, high authority to the contrary notwithstanding; though it is difficult to see why this fact may not very naturally and easily harmonize with the opinion of Goebel by supposing that a secondary reduction, correlated perhaps with the more pronounced development of the sporogonium, has taken place. This position is strengthened by the indubitable fact that analogous reduction has taken place in the sporophyte of some of the Spermatophyta.

Following is a discussion of the structure and development of brood-organs. A circle of interest centers in the paragraph in which it is pointed out that the nematogonal cells (the initial cells which give rise to protonemal structures) preserve their embryonic peculiarities, and regards this as an especially good example of the 'continuity of the germ plasm.'

The special adaptations for the abscission of brood-organs have already been referred to. It may be added that active loosening of the brood-bodies is of very restricted occurrence. In the vast majority of cases the breaking away is passive, depending on the impact of air, water and animals. The same end is held by some observers to be attained through water absorption or drying out, and purely hygroscopic movements. Dissemination may occur by means of air and water currents, and a quite well established case is recorded in which Thysanura were responsible for carrying the brood-bodies of Aulocomnium and Androgynum. The projection of the parts bearing brood-organs above the general levels of the moss-turf is interpreted as an adaptation for dissemination through such animal forms. Hook-like organs occur (*Ephemeropsis* and *Bryum bulbilosum*), which are subject to similar teleological interpretation, though one with difficulty escapes the conviction that the point is somewhat far-fetched. Mucilaginous outer membranes, which insure adhesion to animal forms, are also present in some kinds.

Of the remaining matters perhaps the most important to mention here are the attempt to determine whether correlation occurs between the habit of producing gemmæ and the conditions under which the plants live, and to estimate the taxonomic value of the organs in question.

The typography and numerous illustrations are up to a high standard, but do no more than justice to the thorough work of the author. A full index of generic and specific names extends greatly the usefulness of the volume, which will be of very great value to those botanists who are interested in the biological matters relating to the mosses, but whose studies have not been directed to them in a taxonomic way. It will also serve a good purpose in enabling the student who may be contemplating research in these lines to orientate himself historically. This will be facilitated also by a very complete bibliography.

FRANCIS E. LLOYD.

FROM a systematic standpoint this work is of great value to American students, for of the 110 species described, 52 are known to occur in this country, and 108 out of the 187 figures refer to them. Systematic books have overlooked asexual methods of reproduction except in such cases as *Georgia pellucida*, *Aulacomnion palustre*, *Tortula papillosa*, and a few others where the means were so conspicuous as to defy ignorance; hence it will be a surprise to learn that *Dicranum scoparium*, *Funaria hygrometrica*, *Bryum argenteum* and *Dicranella heteromalla*, though commonly found fruiting, have also methods of propagation. Those species which are conspicuous for their brittle leaves are many of them rare in fruit, forming new plants from the fragments of the leaves, but an interesting addition to the list having this method is *Anomodon tristis*, which thus far is unknown in fruit. The 'Confervæ Orthotrichæ,' those brown septate bodies which occur on the leaves of various species of *Orthotrichum* and *Grimmia*, have long been familiar, but few students have realized why so many species of *Campylopus*, *Tortula*, *Bryum* and *Plagiothecium* were more often found sterile than fertile, nor how they reproduced in spite of this fact. Climates where sexual reproduction is difficult cause a greater development of other methods, and dioicous species are more apt to develop asexual methods than monoicous ones. An artificial key is given by which the asexually propagative species may be classified according to the modifications of the stem, leaves and protonema; it will be useful in encouraging the study and collection of such species as have been ignored or overlooked on account of lack of fruit. The work has paralleled that of F. De Forest Heald, published in the *Botanical Gazette* for 1898, but it is more extensive, and the author claims to have found that *Bryum annotinum*, *Pleuridium nitidum bulbillifera* and *Leptobryum pyriforme* are identical. There is a similar identity between *Pottia riparia* Austin, which antedates *Leptodontium Canadense* Kindb. and *Trichostomum Warnstorfii* Limpr., all of which propagate by clusters of septate propagulæ borne on the paraphyses, seemingly replacing the archegonia, hence all but *Pottia riparia* have thus far been only found sterile. Under whatever genus the species is recognized, that of Austin has priority, a fact to which I have already called attention.

E. G. BRITTON.

N. Y. BOTANICAL GARDENS,
BRONX PARK.

The Physical Nature of the Child and how to Study it. By STUART H. ROWE, PH.D., Supervising Principal of the Lovell District, New Haven, Conn.; formerly Professor of

Pedagogy and Director of Practice in the State Normal School at Mankato, Minnesota. New York, The Macmillan Co.; London, Macmillan & Co., Ltd. 1899. Price, $1.00.

The strictly scientific contribution of this book is rather small, but its practical value is likely to prove very great. It is a *résumé* of many of the important results of recent studies in child psychology and school hygiene, based largely upon such authorities as the *American Journal of Psychology*, the *Pedagogical Seminary*, the *Child Study Monthly*, the *Educational Review*, and the standard books and papers on child study and school hygiene. From a scientific point of view the special contribution of the book consists in the fact that it gives the reaction of a practical teacher to the more theoretical conclusions of psychologists and students of hygiene.

Among the topics considered are the senses, motor ability, nervousness, fatigue, habits of posture, habits of movement, growth and adolescence, and school and home conditions. The more common and simple tests of the senses, of motor ability, nervousness and fatigue are given; and the commonplace teachings in regard to education and health that result from psychological study are presented in a way that is likely to appeal to teachers. The keynote of the book is stated by the author as implied in two fundamental principles of education: "One of these is that action is the first law of growth; the other, that individuals vary enormously in their capabilities for different kinds of mental and physical action."

Very few direct references to literature are made in the body of the book, and the query naturally arises whether in a work so largely based on recent studies in psychology and hygiene even the popular demand for a clean page justifies the omission of explicit reference to authorities. To the scientific student, such a lack is often exasperating, and in this case only partially atoned for by the blanket acknowledgment in the selected bibliography at the end; and some ambitious teachers may wish to know, for example, who besides the author have used the tests for hearing mentioned in chapter 3; upon the results of whose investigations of fatigue are based the suggestions (pages 80–81) 'which we may accept as practically proved'; how the author knows (p. 130) that children grow more rapidly in summer than in winter; and where Eulenberg's table of scoliosis among school children (given on p. 154) can be found. The need of such references to authority is emphasized, for example, by recent investigations upon fatigue which cast discredit upon Griesbach's method, and in many places throughout the book the weight of the author's statements would be increased by direct citation of authority.

WM. H. BURNHAM.

SOUTH AMERICAN LANGUAGES.

Der Sprachstoff der brasilianischen Grammatik des Luis Figueira nach der Ausgabe von 1687. Von JULIUS PLATZMANN. Leipzig, B. G. Teubner. 1899. Octavo. LIV., 247.

Der Sprachstoff der Guaranischen Grammatik des Antonio Ruiz übersetzt und hier und da erläutert von JULIUS PLATZMANN. Leipzig, B. G. Teubner. 1898. XX., 261. Octavo.

Chilidúgu. Lachrymæ salutares opera Bernardi Havestadt. Editionem novam immutatam curavit DR. JULIUS PLATZMANN. Lipsiae, Teubner. 1898. Pp. 78.

Los Indios Matacos y su lengua por Juan Pelleschi, con introduccion por S. S. LAFONE QUEVEDO. Dos mapas. Buenos Aires. 1897. Pp. 246.

The above mentioned publications are not facsimilarian editions of authors such as Dr. Platzmann is in the habit of issuing, but explanations in the form of translations and commentaries of vocables and grammatic forms recorded in books now difficult to obtain. Guarani and Tupi are dialects of the same family very closely related, and at the time these missionaries were composing their works Guarani was heard not only along the eastern border of Peru, but also along the La Plata, in Paraguay and on the coast of Brazil.

According to the most reliable sources Luis Figueira was born in the Portuguese province of Alemtejo in 1575, entered the seminary of Evora in 1592 and went over to Brazil in 1602. He settled in Maranhão in 1607 to found missions for the conversion of the natives, and by the year 1615 the knowledge he had acquired of Guarani enabled him to compose his 'Arte de Grammatica' of the 'Brazilian' or Guarani language. He was on the return trip to the mother country, Portugal, when he became shipwrecked at the mouth of the Amazonas, at Marajó Island, attacked by the Aroan savages and put to death on July 6, 1638.

The main part of Platzmann's volume is followed by a series of 1991 Guarani terms of Figueira translated and commented upon in German. In reading this list we often wish to have the original of the *Arte* in hand for reference.

In the preface Platzmann discusses the phonetics of that language and the characters used by the *Padre* to express certain sounds. There are also literary sketches on previous and recent Portuguese authors on Brazil, its Indians and their languages, and on the area in which Tupi is spoken at present.

Another apostle of the Roman Catholic faith among the Brazilian tribes was Antonio Ruiz de Montoya. He was born in Lima, 1583, and died there in 1652; therefore he can be considered as an American-born missionary. His earliest work appears to have been the Tesoro, a Guarani-Spanish dictionary of 814 pages, which saw the light in Madrid, 1639. This was followed next year by the *Arte* or grammar of Guarani, the Vocabulario and the Catecismo; this last was reprinted by Platzmann in 1876. The words of the language are presented, analyzed and translated in 2236 items. This part of the volume is instructive, but the part of Platzmann's preface in which he compares Guarani radicals with those of European languages contains too many fanciful ideas to meet general approval.

Having previously republished Bernard Havestadt's 'Tractatus de lingua Chilensi,' in two volumes, Dr. Platzmann was informed that his publications of Havestadt's 'Opera' were not complete without his 'Lachrymæ salutares.' So he set himself to commit this Latin religious poem, although it has nothing to do with Indian philology, to press. It is written in fine trochaic verses, which were in vogue in his time for church poetry.

Juan Pelleschi is a civil engineer, who wrote his book in Italian and had it translated in Spanish. He treats of the customs and manners of the Matacos or Mataguayos, a roving people inhabiting the Gran Chaco, not in a strictly scientific manner, but in a colloquial way. This may be said also of his treatment of the Mataco language, which is identified with the Tonocoté. We find no paradigms of nouns or verbs, no rules, exercises, etc., but the character of this tongue is developed at length and in a general way without any strict plan or method. Of the two maps the first is a reproduction of an ancient map and exhibits in an excellent manner the early distribution of tribes on the Gran Chaco. A Spanish-Mataco and a Mataco-Spanish vocabulary concludes the publication.

ALBERT S. GATSCHET.

SOCIETIES AND ACADEMIES.

THE PHILOSOPHICAL SOCIETY OF WASHINGTON.

AT the 508th meeting of the Society, held on December 9th, at the Cosmos Club, biographical sketches of Mr. Edward Goodfellow and of George Brown Goode, were read; the former by Mr. H. G. Ogden, and the latter by Mr. Cyrus Allen. The regular papers of the evening were by Mr. E. D. Preston on the 'Language of Hawaii,' by Mr. F. H. Bigelow on 'Results of Recent Exploration of the Upper Atmosphere,' and by Mr. G. W. Littlehales on 'Possible Methods of Measuring the Resultant of the Centrifugal and Gravitational Forces on the Ocean.' The first paper dealt with the Polynesian languages in general and the Hawaiian in particular, from the standpoint of comparative philology. Similar constructions were followed out in the Oceanic and Indo-European tongues, and points of contact were noted between modern Hawaiian, on the one hand, and French, German, Spanish, Italian and English, on the other. In the last paper the author, after recounting the trials that were made by Mascart, nearly twenty years ago, to determine the variation of the force of gravity from place to place by means of a siphon barometer whose short arm was closed and contained a certain quantity of gas, referred to the experiments that have lately been made by Mohn of Christiania, according to a method that was reported to the U. S. Coast and Geodetic Survey, in 1890, by

Assistant Superintendent Tittmann, with a view to finding the gravitational correction in mercurial barometric readings by comparing the atmospheric pressure as indicated by the mercurial column with the true atmospheric pressure as deduced from the temperature of unconfined steam. He then proceeded to relate his own considerations and experiments concerning the possibility, in times of exceptional calm at sea, of using the Electric Clepsydra for the measurement of the relative quantities of mercury discharged in equal intervals of time at different places from an orifice in the bottom of a vessel of comparatively large cross-section, and also concerning the possibility of ascertaining the changing relation, with change of place between a given mass, and its weight, by the use of a modification of the standard aneroid barometer in which the vacuum chamber has been replaced by a heavy mass.

E. D. PRESTON,
Secretary.

ANTHROPOLOGICAL SOCIETY OF WASHINGTON.

THE 296th regular meeting of the Society was held Tuesday evening, December 5, 1899.

Miss Alice C. Fletcher read a paper on 'The Building of the Earth Lodge' describing its minute structure, purpose and variety.

Dr. Washington Matthews read a paper on 'The Earth-Lodge in Art,' in which he stated that the earth-lodge was the most commodious aboriginal structure existing in America north of New Mexico. Henry in 1807 measured one in the old Mandau Village at Knife River which was 90 feet in diameter. Thousands of such lodges, inhabited by tribes of widely different stocks, existed in the Mississippi Valley at the time of the Columbian discovery ; their remains are scattered from North Dakota to Louisiana and from Western Kansas to Eastern Tennessee.

Dr. Matthews stated that the embellishments in works of ethnography and travel were often false, and tended to lead the student astray rather than to aid him. He gave a number of general instances of false illustration in ethnography, but spoke chiefly of the misleading pictures of the earth-lodge published in various works. He exhibited pictures taken from the works of Gass, Catlin, De Smet and Morgan, and compared them with photographs of the real lodge. The most faithful pictures of the lodge not photographic were those of Mr. Bodmer, the artist who accompanied the Prince of Méd.

Mr. Jas. Mooney read a paper entitled 'The Earth-Lodge in the Gulf States.'

J. H. MCCORMICK,
Secretary.

BIOLOGICAL SOCIETY OF WASHINGTON.

AT the 314th meeting on December 16th, Lester F. Ward spoke of 'the Fossil Forests of Arizona,' saying that they were of Mesozoic age, the strata containing the petrified trunks ranging from just above the Permian up to and including the Upper Trias; the formation extended northwards into Utah. The territory in which the petrified forest lay was in Apache Co., east of Holbrook, but while the trunks were found over a very considerable tract the best portion of the 'Forest' was embraced in an area about eight miles square. In some portions of this the petrified logs lay much more thickly than they could have stood when living. In fact these trees did not lie where they had grown, but had been transported thither in Mesozoic time by strong and swift currents and had then been rapidly buried in sand. The trees were completely silicified and so well preserved that the microscopic structure could be clearly made out, showing that they were related to the Araucarian Pine of the Southern Hemisphere; hence the genus had been named *Araucari oxylon.* The speaker stated that his recent visit to the petrified forest was the result of a request from the General Land Office for a report as to the desirability of reserving the most interesting portion as a national park, a memorial to Congress to that effect having passed the Legislature in 1895. Owing to the visits of tourists, the more beautiful specimens were being steadily carried away and destroyed, while many car loads had been removed to be cut, polished and made into ornaments. Owing to the extreme hardness of the silicified trunks, it had been proposed to utilize them in the manufacture of a substitute for emery, and a crushing plant had actually been erected, although never operated, owing to the development of the corundum industry in Canada.

Ex-Governor W. A. Richards, Assistant Commissioner of the General Land Office, who was present and was invited to speak, said that the Land Office was in earnest in this matter and was glad to have a truly scientific report on the subject. He stated that a very large amount of the material was now being worked up in this country into articles to be sold at the coming Paris Exposition.

F. A. Lucas described 'Blue Fox Trapping on the Pribilofs,' saying, that Mr. James Judge, Treasury agent on St. George Island, had experimented extensively in the feeding and trapping of foxes, and had devised methods by which they could be readily taken alive, so that the females could be liberated, as well as a certain proportion of the males, the other males being killed. The entire paper will appear in SCIENCE.

M. B. WAITE described a 'Soil Inoculation Experiment with Soy Beans,' in testing the effect of imported Japanese soil on the Soy bean. This plant is a native of Japan and in that country forms root tubercles abundantly. In this country the plants commonly do not form root tubercles, for the reason that the necessary germs do not exist in American soils. The Soy bean is thus unable to gather free nitrogen after the manner of other Leguminosæ.

Soil was imported from a Soy bean field in Japan and sown in small quantities in the drill with the seed. The experiment was tried on a newly cleared piece of sandy land poor in combined nitrogen, and the results were quite striking. The plants in the control rows at harvest time plainly showed nitrogen starvation. In the rows inoculated with Japanese soil the plants were larger, leafier and darker green in color. They showed the effects of nitrogen fertilization. On examining the roots they were found to be well supplied with the nitrogen, gathering tubercles, while the check plants had few or none. The comparative weight of the treated and untreated portions was as 14 to 8 in favor of the treated plants.

O. F. COOK,
Secretary.

ONONDAGA ACADEMY OF SCIENCE.

THE November meeting of the Academy was addressed by Dr. J. M. Clarke, the New York State paleontologist. He gave briefly a history of the work accomplished by the geological survey of the State from its inception in 1842 to the present time, and explained in detail the new system of nomenclature proposed for the State, giving reasons for accepting the same. The latter part of the address was devoted to an account of the transitional fauna of the Portage and Chemung formations.

At the meeting of the Geological Section Mr. C. E. Wheelock read a paper on 'The Marls of Onondaga County.' He showed that the principal deposit crossed the county just north of its center and in an east and west direction, corresponding quite closely with the southern extent of the extinct Lake Iroquois. The beds in the western part of the county were studied in detail, and would seem to bear out the theory that there had occurred several oscillations of the lake shore. Excavations within the limits of Syracuse seem to corroborate the same theory. Mr. Wheelock believed that this marl deposit was cotemporaneous in formation with the existence of Lake Iroquois. The few isolated and small deposits in other parts of the county he held to be of different and probably more recent formation.

At the December meeting Dr. W. M. Beauchamp spoke on local archæology. He said that the village sites and their approximate dates of occupation could be traced by the relics found on the various sites. As the Onondagas occupied usually only one village, their migrations are more easily traced than tribes consisting of several villages. The occurrence of implements of walrus tusks, and also a peculiar variety of stone knife, prove beyond reasonable doubt that the Eskimos were earlier inhabitants, even if only temporary, than the Indians.

Dr. W. G. Hinsdale described the character of relics found on local sites, speaking more particularly of the harpoons, barbed fish-hooks and other polished bone implements. Grooved axes are only rarely found in this section, and implements are seldom found buried with the skeletons unearthed.

H. W. BRITCHER,
Corresponding Secretary.

THE PHILOSOPHICAL SOCIETY OF THE UNIVERSITY OF VIRGINIA.

THE regular monthly meetings of this society have begun. At the first meeting of the present session the following officers were elected for the current year:

President, Dr. C. W. Kent; Vice-president, Professor W. H. Echols; Secretary, Dr. W. J. Humphreys.

After the election of officers, Professor Ormond Stone delivered the customary address of the retiring president. His subject was *The Moon*. His address, supplemented by many excellent photographs, was a clear presentation of the more recent theories in regard to the markings on the moon's surface, and probable past and future history of the moon's relation to the earth.

The second meeting, December 8th, was devoted to meteors. Professor Ormond Stone gave a brief outline of the preparations made under the auspices of the Leander McCormick observatory for studying the Leonid meteors. These included, among other things, six photographic stations on a north and south line about forty miles in length.

Dr. M. W. Humphreys explained his methods of making and recording eye-observations of meteors, and called attention to several very singular meteors--about half a dozen in all--seen on the nights of November 14th and 15th. These were all red and moved in wavy lines, the amplitudes being approximately one degree. It was admitted that this might be an optical illusion, but if so, not peculiar to the observer, as in the case of the most conspicuous meteor of this type the same phenomenon was noted by at least one other member—a young lady—of the party.

Dr. W. A. Lambeth gave an account of a shower of meteors he saw in November, 1892, in North Carolina. He said it was about eleven o'clock at night and that they appeared far too rapidly to allow even a guess at the number—that they presented the appearance of a veritable rain of fire, so much so that for a time the engineer of the train he was on refused to run his engine, and that the negroes, as in 1833, indulged in song and supplication, believing firmly that the end of the world had come.

Mr. J. A. Lyon gave a short history of the Leonid meteors, covering a period of about one thousand years.

Dr. W. J. Humphreys, described the photographs obtained, all of which, with possibly one exception, failed to show meteor trails. Several practical points were learned, however, and these were stated in view of the fact that renewed efforts will be made next year to photographically determine the radiant and the height of the atmosphere.

At the close of the meeting Professor F. L. O. Wadsworth, director of the Allegheny Observatory, showed to those interested a curved star negative of Orion and adjacent regions which he had recently taken. This remarkable negative, due to the combined skill of Wadsworth and Brashear, has, in excellent definition, more than one thousand square degrees, and shows, according to their estimation, more than 50,000 measurable stars.

W. J. HUMPHREYS,
Secretary.

ALABAMA INDUSTRIAL AND SCIENTIFIC SOCIETY.

THE regular autumn meeting of the society was held in the rooms of the Commercial Club, in Birmingham, on the afternoon of November 16, 1899.

Mr. T. H. Aldrich, ex-president of the society, in the chair. Present, Messrs. J. A. Montgomery, B. B. Ross, Col. Horn, E. A. Smith and representatives of the press. The reading of the minutes of the last meeting (annual) was dispensed with, as the proceedings of this meeting had already been printed and distributed. The Secretary made the statement that on the occasion of the spring meeting so few members and officers were present that it was decided not to have a meeting, notwithstanding the fact that Dr. Ross was present with a paper and Mr. James Bowron had consented to talk to the Society about Cuba.

After the regular routine, Dr. Ross gave an abstract of his paper on 'The Fertilizer Resources and Fertilizer Industries in Alabama.' This valuable paper will be printed in full in the Proceedings. Dr. Ross also exhibited to the members a number of samples of phosphate rock collected recently by him in the vicinity of Athens, in Limestone County. The samples analyzed by him contained from 15 to 20 per cent. of phosphoric acid up to 36 or 37 per cent.; and he also showed a sample of superphosphate prepared by him from this rock, the manufactured article containing 13.15 per cent. water—soluble, 0.15 per cent. reverted, and 1.24 per cent. insoluble; total 14.9 per cent. phosphate.

In the discussion which followed, Mr. Aldrich said that a fertilizer manufactory in Meridian was using lignite from the Burning Cut in Sumter County, Ala., as a filler, and that it contained 1.5 to 2.0 per cent. ammonia. Mr. Aldrich had formerly sold from the Blocton mines several hundred tons of coal slack, to a Shreveport company, for the same uses. He also mentioned the fact that he had recently examined a lignite occurring in Mississippi, 17 miles west of Starkville, which had only 4.5 per cent. of ash and which made a very good coke.

Dr. Smith then read a preliminary report of the mineral statistics of Alabama for the second and third quarters of the current year; after which, there being no other business before the meeting, it was adjourned *sine die*.

EUGENE A. SMITH,
Secretary.

DISCUSSION AND CORRESPONDENCE.

DR. WILSON'S REPLY TO HIS CRITICS.

I CONSIDER it complimentary to an author that his works should be criticised. It shows that they are worthy of attention and consideration. The friendly criticism in SCIENCE, December 22d, of my address delivered in Columbus last August, before the Section of Anthropology of the A. A. A. S., appears under such misapprehension as seems to require a word of explanation. That address, as its title indicates, was 'A History of the Beginnings of the Science of Prehistoric Archæology.' It was a *résumé* or description of the discoveries made, or alleged to have been made, which led to the foundation of the science, and a statement of the theories advanced for its establishment. This being its purpose, it was proper that I should treat of all its topics, and this without binding me to an approval of them. I was recording a history of the science, not necessarily maintaining the truth of all the theories advanced by its founders. The friend who wrote the criticism seems not to have recognized the difference. He makes strenuous opposition to the classifications of the science as set forth in my address; but none of them were mine. They had been made in Europe many years since, were applicable to that country, and most of them are still in use there. In such a history as I was writing it would have been highly objectionable for me to have omitted them; and so with most of the other points in the criticism referred to.

THOMAS WILSON.

NOTES ON INORGANIC CHEMISTRY.

AN important practical application of the liquefaction of hydrogen is that of the production of high vacua, as described by Dewar in the *Proceedings* of the Royal Society. At the boiling point of hydrogen the vapor tension of air is less than a millionth of an atmosphere, hence when to vacuum tubes for the spectroscopic examination of gases is attached a temporary tube immersed in liquid hydrogen, the solidification of the air in the tube produces a very high vacuum. In this way the more volatile constituents of atmosphere become concentrated in the tube, and in numerous tests the presence of neon and of helium was revealed in a volume of air less than 50 cc. Some tubes showed a hydrogen spectrum, but others did not, so that the question as to whether free hydrogen exists in the atmosphere cannot be considered as settled.

A LATER number of the *Proceedings* contains a paper by T. G. Bonney on the parent-rock of the South African diamonds. The 'blue ground' of the Newlands mines, which are forty miles northwest of Kimberley, contains rounded boulders of eclogite, and in this eclogite are occasional colorless octahedra of diamond, apparently as an original constituent. As the eclogite boulders are water-worn, it follows that the 'blue ground' is not of igneous origin, but it is true breccia produced by the destruction of various rocks, one of which—the eclogite—has contributed the diamonds to the mixture.

THE analysis of a sample of Egyptian porcelain from Memphis is published by Le Chatelier in the *Comptes Rendus.* The composition is found to be wholly different from that of Chinese porcelain, and hence it would appear that the manufacture of true porcelain was known to the ancient Egyptians. The duplication of this Egyptian porcelain would require 40 parts blue glass, 50 parts fine sand, and 5 parts white clay.

Le Chatelier has also examined statuettes from Egyptian tombs which were supposed by Salvétat to be carved from a natural grit and then glazed with a sodium-calcium-copper silicate. It appears, however, that the statuettes from several different localities consist chiefly of fine grains of quartz sand, with a little clay as a binding material. The glaze is a mixture of sand with a sodium-copper silicate.

The effect of sulfur, especially as pyrites, in coal when used as a fuel is discussed by Wilhelm Thörner in the *Chemiker-Zeitung.* With such a fuel, not only sulfur dioxid, but also sulfuric acid will be present in the combustion products. Since at least a portion of this sulfuric acid will be deposited upon the boiler walls, tubes, etc., it is necessary that these should be cleaned frequently. The more moisture present, the greater the corrosive action of the acid. If lime is mixed with the coal, the formation or at any rate the deposition of the acid is in large part prevented. The author suggests the use of briquettes made of an intimate mixture of coal with a little lime. With these not only can fine coal screenings, slack, etc., be used, but sulfuric acid corrosion may be practically avoided.

J. L. H.

CURRENT NOTES ON PHYSIOGRAPHY.

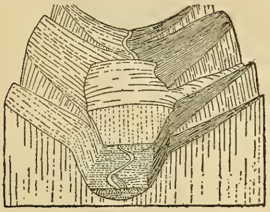
In resuming the preparation of these notes after an interruption of a year and a half, it will not be possible to mention all the physiographic essays published in the interval, but the effort will be made to give account of the more important ones in which the readers of Science may be interested, as well as to review current publications.

GLACIAL SCULPTURE IN WESTERN NEW YORK.

Gilbert concludes that the Niagara limestone upland in western New York is chiefly a product of pre-glacial erosion, but that its relief has been increased by the greater glacial erosion of the lowland underlaid by weaker shales on the north, and that its northward-facing escarpment has been modified in detail by glacial action. Where the escarpment faces northwesterly, so that the ice sheet moved about parallel to its front, the outline has been smoothed; where it faces northeasterly, against the ice motion, preglacial irregularities are intensified by glacial scouring. The plain of Medina shale bordering Lake Ontario, and now overspread with drift and lacustrine strata, has a broadly furrowed rock floor, with troughs parallel to the ice motion: here the minimum estimate of the general reduction of the surface by glacial erosion is set at 40 or 50 feet, 10 or 20 times its measure on the limestone upland (Bull. Geol. Soc. Amer., X., 1899, 121–130).

GLACIATED VALLEYS.

The most original physiographic essay presented to the recent International Geographical Congress at Berlin was one by Penck on the over-deepened valleys of the Alps. Not only where large lakes occur near the margin of the mountains, but far inward along the larger rivers, the main valley floors are deepened below the level of the side valley floors and the discordance thus indicated is ascribed to the stronger glacial erosion in the main than in the side valleys. The side streams plunge down into the main valley as waterfalls. This discordance of valley floors at first seems exceptional, characterizing valleys of glacial erosion but not of river erosion: but it was well shown that there is no such failure of analogy. A river of water moves nimbly; its cross section is small and its channel is a small part of its valley; the river bed is usually hidden, and hence, as main and side streams have the same surface level at their junction, we do not ordinarily notice that the bed of the main river channel is deeper than that of a side stream, although this relation must be recognized as soon as attention is turned towards it. A river of ice moves slowly; its cross section is large and its channel is a large part of its valley; ancient glacial channels are now habitually laid bare, and the discordance between the beds of the main and the tributary channels becomes very striking, while we lose sight of the accordance that must have prevailed in the confluent



surfaces of the main glacier and its tributaries. The river channel as well as the glacial channel is U-shaped, but the abandoned glacial channel is so large that it often gives name to the valley in whose bottom it is eroded. The accompanying diagram roughly presents the form of an Alpine valley in preglacial (background), glacial (middleground), and postglacial (foreground) time.

THE heavy glaciation of valleys eroded in the massive gabbros of Skye has produced the following features, as noted by Harker (Geol. Mag., London, 1899, 196–'99). The cross-section of the valleys is U-shaped, especially in their upper part. The head of the valley expands in a corrie (cirque or amphitheatre) whose floor is often a rock-basin holding a tarn. In longitudinal profile, the floor of a valley often consists of two or three stretches of relatively gentle slope (or even of basin-form) separated by relatively sudden descents. Tributary valleys mouth at a considerably higher level than the floor of the main valley. McGee's paper on 'Glacial Cañons' (*Journ. Geol.*, II., 1894, 350–364), referred to by Harker, may be read to advantage in this connection.

It is noteworthy that the discordance of side and main valleys, emphasized by Penck as a characteristic of glacial action, and clearly recognized by McGee and Harker, has been mentioned in but few essays on glacial erosion; yet it can hardly be doubted that such discordance is one of the most striking features of strongly glaciated mountain regions.

ANCIENT VALLEYS OF NORTHEASTERN GERMANY.

THE origin of many broad valleys in northeastern Germany, as determined by ancient rivers flowing westward, marginal to the retreating ice-sheet of the last glacial period, has lately been restated by Keilhac (*Verh. Gesellsch. Erdk.*, Berlin, XXVI., 1899, 129–139, map), with fuller detail than was given in the earlier explanations by Berendt and Girard. Five important valley courses are traced, exterior to five morainic belts; the southernmost connects the Oder at Breslau with the Elbe above Magdeburg; the northernmost led the Oder from Stettin northwest to Ribnitz and south again from Lübeck to the Elbe at Lauenburg. Lakes are indicated by horizontal shore-terraces at certain depressed areas along the valley courses, where the present northward discharge was ice-barred. The ancient ice-margin valleys owe their considerable breadth to the large volume of the rivers that were then supplied by melting ice on the north as well as by rainfall on the south. The rivers of to-day follow the ancient marginal valleys for moderate distances only, and then turn northward through depressions that were opened to them as the ice melted back; sometimes again turning westward for a stretch along the next marginal valley that is encountered. Thus sub-rectangular bends to the right and the left are systematically repeated seven times by the Oder, between Breslau and Stettin.

W. M. DAVIS.

ZOOLOGICAL NOTES.

MR. C. W. ANDREWS, in a recently issued part (Vol. XV., part 3), of the Transactions of the Zoological Society of London, describes at length and figures the skull and portions of the skeleton of *Phororhacos inflatus*, one of the gigantic extinct Patagonian birds. In discussing the relationship of the genus, which is put among the *Gruiformes*, Mr. Andrews shows a decided leaning toward *Cariama*, saying that the relations of the one toward the other are much the same as those of the extinct *Glyptodon* and *Panocthus* towards existing armadillos. Mr. Andrews will be glad to know that among the material obtained for Princeton University by

Mr. J. B. Hatcher, is a small species of *Phororhacos*, or some closely allied genus, in which the sternum is preserved, that this sternum is slightly keeled, and, although no critical comparisons have been made, that the general aspect of the sternum is like that of *Cariama* or *Gypogeranus*. F. A. L.

THE MALARIA EXPEDITION TO WEST AFRICA.

Major Ronald Ross, the lecturer to the Liverpool School of Tropical Diseases, who recently headed the malaria mission to Sierra Leone, delivered an address on December 27th at Liverpool, on the invitation of the African trade section of the Liverpool Chamber of Commerce. His subject was 'The Recent Medical Expedition to West Africa.' According to the London *Times* Major Ross said that politics and science were culminating in two movements of high importance. In politics the Great Powers, tired of self-development, were endeavoring to extend their possessions and civilization all over the world; while in science they had created what was perhaps the most fundamentally important of all knowledge—the experimental science of disease. He believed that in the coming century the success of Imperialism would depend largely upon success with the microscope. Our possessions in Africa were battle grounds between Englishmen and king malaria: they were conquests maintained only at the sacrifice of hecatombs of our countrymen. Malarial fever was perhaps the most important of the diseases of the tropics. For a long time they could obtain no accurate knowledge as to how the disease was produced, but in the last two years they had ascertained definitely at least one mode of infection. They knew for certain that malarial fever was often, perhaps always, caused by the bite of the species of gnat or mosquito called anopheles. The object of the expedition from the Liverpool School of Tropical diseases was to ascertain whether there was any chance of exterminating the anopheles from a given malarious area. It was not the immediate purpose, as some supposed, to banish malaria then and there from the whole continent of Africa. They wished to inquire what could be done in two or three square miles. They selected Free Town, Sierra Leone, for the investigation, and reached there last August. After describing Free town, Major Ross said that the mission set themselves to work at once on the lines of the recent investigations in India and Italy. In a few days they found numbers of the anopheles, and in a few days more they discovered the germs of malaria actually within those insects. They knew then to an absolute certainty that the anopheles of Sierra Leone were responsible at least for a large part of the fever there. The next thing was to ascertain how they bred. Those very dangerous insects bred in small pools or puddles of a certain kind easy to detect when one had once seen them. They made a map of those pools and carefully studied the habits of the insects' larvæ. The conclusion they unanimously came to was that it would probably be an easy and inexpensive matter to rid the town almost entirely of the anopheles either by destroying the larvæ in the puddles or, bettter still, by draining away the puddles altogether.

Comparing the general mode of life of Europeans in Sierra Leone and India, Major Ross said that, though Sierra Leone was scarcely more fatal to Europeans than some parts of India, it was certainly much more unhealthy than the large majority of Indian towns and cantonments were. He confessed that after a service of many years in India and Burma he was much struck with a certain negligence in respect to some matters in Africa. In India Englishmen had learned how best to live in tropical countries. They had certain fixed institutions which they seldom did without. He referred to the commodious bungalow, with its large compound, the punkah, and the mosquito netting on the beds. There was no doubt all those were of great assistance, but in Sierra Leone he was astonished to find none of those things, at least in general use. Instead of there being a separate European quarter on the highest ground available and consisting of well-built houses each in the midst of an open garden, most Europeans in Freetown occupied poor wooden structures quite unfit for English people in that pestiferous climate, crowded together and mingled with the houses of the townspeople (who had not the same reason to dread the malaria), and in the very lowest, dampest and hottest part of the town. The Governments and the great commercial houses who sent *employés* to the tropics and paid their expenses—especially their funeral expenses, which were considerably larger than the mere cost of the hearse—should have something to say on the matter. The nation had not paid sufficient attention to the shocking mortality in its tropical possessions. They shuddered to hear of a few guinea-pigs being inoculated with disease in the laboratory, but looked on with indifference at the infection by natural means of thousands of their countrymen and of millions of our colored subjects in the tropics. They spent floods of money in the tropics on what was called sanitation and maintaining costly medical service, but such expenditure was more or less perfunctory; it was part of the Budgets, and it was allocated without much intelligence, and he feared, largely wasted. Fifty years ago a new parasite called the ankylostoma duadenale was discovered. It was now known, chiefly as the result of investigation by private persons, to cause an immense amount of sickness and mortality among our colored subjects. Although the presence of the parasite could easily be detected by the microscope, its name hardly found a place in our statistics of disease. A few years ago Giles studied the mode in which it gained an entry into our bodies. Since then no one had repeated his observations or taken the slightest interest in them. It had not been thought worth while to check the ravages of that disease. Again, some years ago a parasite was found which might perhaps cause that terrible and widespread disease, dysentery. No attempt had been made by Englishmen to clear up that important point; and the life-history of the parasite which was studied years ago by Cunningham seemed to have been completely forgotten. Twenty years ago Manson ascertained that the parasite which caused elephantiasis was carried by the mosquito. Until last year not a single person had made any adequate attempt to verify his work—much less to act upon it for the prevention of the disease. In India alone the mortality ascribed to fever was five million persons annually. Besides the mortality vast tracts of fertile possessions were rendered uninhabitable by this disease. Twenty years ago the parasite which caused the disease was found, but not a microscope or pen was used by Englishmen for seven years. During those seven years 35 million persons died from fever in India alone. Then a single Englishman, Vandyke Carter, took up Laveran's discovery. He was now dead. For that and other noble work he received no reward. Not another Englishman moved in the matter for another seven years, lazy, indifferent, and imbecile scepticism holding the ground. Then a few young countrymen of ours commenced to study the subject, years after other great nations had been attacking it with vigor, and now they did find medical men and others who paid some attention to it in the British dominions. Now there was an awakening everywhere. The Royal Society itself, assisted by Mr. Chamberlain and the Colonial Office, had taken up the matter with energy. The tropical schools of London and Liverpool had been founded by leading citizens, and scientific missions were being sent to different parts of the world. He had spoken that day in the hope of increasing sympathy in the great cause. A thousandth part of the energy now spent on numberless philanthropic schemes in Great Britain was likely at that moment to produce a thousand times as much fruit if properly expended in the cause of imperial sanitation. They had much reason to hope that in a year or two they would not only have a complete knowledge of how malaria was produced, but would foresee a cheap and practical mode of prevention.

NAVY REPORT ON WIRELESS TELEGRAPHY.

THE U. S. Navy Board has reported on the Marconi system of wireless telegraphy as follows: It is well adapted for use in squadron signaling under conditions of rain, fog, darkness and motion of speed. Wind, rain, fog, and other conditions of weather do not affect the transmission through space, but dampness may reduce the range, rapidity and accuracy by impairing the insulation of the aërial wire and the instruments. Darkness has no effect.

We have no data as to the effects of rolling and pitching, but excessive vibration at high speed apparently produced no bad effect on the instruments, and we believe the working of the system would be very little affected by the motion of the ship. The accuracy is good within the working ranges. Cipher and important signals may be repeated back to the sending station, if necessary, to insure absolute accuracy. When ships are close together (less than 400 yards) adjustments easily made of the instruments are necessary. The greatest distance that messages were exchanged with the station at Navesink was 16.5 miles. This distance was exceeded considerably during the yacht races, when a more efficient set of instruments was installed there. The best location of instruments would be below, well protected, in easy communication with the commanding officer. The spark of the sending coil or of a considerable leak, due to faulty insulation of the sending wire, would be sufficient to ignite an inflammable mixture of gas or other easily lighted matter, but with the direct lead (through air space, if possible) and the high insulation necessary for good work, no danger of fire need be apprehended.

When two transmitters are sending at the same time, all the receiving wires within range receive the impulses from transmitters, and the tapes, although unreadable, show unmistakably that such double sending is taking place. In every case, under a great number of varied conditions, the attempted interference was complete. Mr. Marconi, although he stated to the Board before these attempts were made that he could prevent interference, never explained how nor made any attempt to demonstrate that it could be done. Between large ships (heights of masts 130 and 140 feet) and a torpedo boat (height of mast 45 feet), across open water, signals can be read up to seven miles on the torpedo boat and eighty-five miles on the ship. Communication might be interrupted altogether when tall buildings of iron framing intervene. The rapidity is not greater than twelve words per minute for skilled operators. The shock from the sending coil of wire may be quite severe and even dangerous to a person with a weak heart. No fatal accidents have been recorded. The liability to accident from lightning has not been ascertained. The sending apparatus and wire would injuriously affect the compass if placed near it. The exact distance is not known and should be determined by experiment. The system is adapted for use on all vessels of the navy, including torpedo boats and small vessels, as patrols, scouts and despatch boats, but it is impracticable in a small boat. For landing parties the only feasible method of use would be to erect a pole on shore and then communicate with the ship. The system could be adapted to the telegraphic determination of differences of longitude in surveying. The Board respectfully recommends that the system be given a trial in the navy.

SCIENTIFIC NOTES AND NEWS.

WE record with much regret the death of Dr. Elliott Coues, the eminent naturalist, on December 25th, in his 57th year.

A MEMORIAL meeting in honor of the late Daniel G. Brinton will be held in Philadelphia on January 16th, under the auspices of the American Philosophical Society, and with the coöperation of some twenty-four societies. A portrait of Dr. Brinton, a memorial medal and a set of his works will be presented to the Philosophical Society.

PROFESSOR E. B. WILSON, of Columbia University, has been elected president of the American Society of Naturalists, in succession to Professor W. G. Farlow, of Harvard University.

DR. WILLIAM MCMURTRIE, of New York City, has been elected president of the American Chemical Society, in succession to Professor Edward W. Morley.

THE New Year's honors annually conferred in Great Britain include a peerage for Sir John Lubbock, a knighthood for Dr. T. Lauder Brunton, the physiologist, and a K. C. B. for Captain W. de W. Abney, the physicist, assistant Secretary of the Science and Art Department.

A MOVEMENT has been started in Baltimore to pay some special tribute to President Daniel Coit Gilman of Johns Hopkins University, in honor of the twenty-fifth anniversary of his connection with the University, which occurred on December 31st.

PROFESSOR C. H. EIGENMANN, director of the Indiana University Biological Station, since its establishment, has severed his connection with the Station, and Dr. R. E. Lyons, professor of chemistry, has been appointed as his successor.

PROFESSOR R. W. WOOD of the University of Wisconsin, has accepted an invitation to lecture before the Royal Photographic Society, London, and will leave New York early in January to be absent about six weeks.

PROFESSOR WILLIAM JAMES, of Harvard University, and Professor G. T. Ladd, of Yale University, have been elected delegates from the American Psychological Association to the International Congress of Psychology meeting next year at Paris.

DR. J. W. GREGORY, of the Natural History Museum, South Kensington, has been appointed to the chair of geology in the University of Melbourne, vacant by the death of Sir. J. M'Coy. It is an open secret that Dr. Gregory applied for the post because the trustees of the British Museum refused to recommend him for the position of a first-class assistant, while they at the same time checked the flow of promotion by retaining Henry Woodward as head of the Geological Section of the Museum after the time for his retirement under the age limit. Dr. Gregory will receive four times the salary at Melbourne that he has been receiving at the British Museum, and will have excellent opportunities for research in Victoria. It appears, however, that the trustees of the British Museum have made a serious mistake in refusing to promote from a second-class assistantship a naturalist whose work as explorer and scientific investigator has already won him distinction, and whose services to the Museum during the past twelve years have been most important.

MR. JAMES LYMAN WHITNEY, who for over thirty years has been connected with the Boston Public Library, has been elected librarian in the place made vacant by the removal of Mr. Herbert Putnam to the National Library, Washington. Mr. Whitney is a brother of the late Josiah D. Whitney, professor of geology at Harvard University, and of the late William Dwight Whitney, of Yale University.

A CABLEGRAM from London announces the death of Sir James Paget, the distinguished surgeon. He was born at Great Yarmouth, January 11, 1814, being the son of a merchant of that city. In 1836 he became a member of the Royal College of Surgeons, and seven years later, after he had made a reputation by some novel and brilliant operations, he was made an Honorary Fellow of the Institution. Among his works are the 'Pathological Catalogue of the Museum of the College of Surgeons,' 'Report of the Results of the Use of the Microscope,' published in 1842, and 'Lectures on Surgical Pathology,' published in 1853, 1863 and 1868. He was also an extensive contributor to the 'Transactions' of the Royal Society, of which he was a Fellow. In 1875 he was elected President of the Royal College of Surgeons, and from 1884 to 1895 he was Vice-Chancellor of the University of London. He was created a Baronet in August, 1871.

THE following have been elected officers of the Society for Plant Morphology and Physiology for the coming year: *President*, Dr. D. P. Penhallow, McGill University, Montreal; *First Vice-President*, Dr. Roland Thaxter, Harvard; *Second Vice-President*, Dr. Erwin F. Smith, Washington, D. C.; *Secretary*, Dr. W. F. Ganong, Northampton, Mass.

THE officers of the American Psychological Association for the ensuing year are: *President*, Professor Joseph Jastrow of the University of Wisconsin; *Secretary*, Dr. Livingston Farrand of Columbia University; *Council*, Professors Ladd, Bryan, Gardiner, Cattell, Delabarre and Kirschmann.

THE members of the American Society of Naturalists voted to invite the members of the American Society, at present in session at Chicago, to constitute the Western branch of the American Society of Naturalists.

THE Society of Gymnasium directors, which met in New Haven last week, will hereafter be affiliated with the societies meeting with the Naturalists. The question of uniting with the Anthropological Section of the American Association was referred to a committee.

A JOINT meeting of the Philadelphia County Medical Society, and the Pennsylvania Society for the Prevention of Tuberculosis will be held at the New Century Club on Wednesday, January 10th. Prominent speakers, both medical and lay, will take part in the discussion. Among the speakers are Dr. Otis, of Boston, Dr. Osler, of Baltimore, and Judge Ashman, of Philadelphia.

THE post of assistant physician in the government Hospital for the Insane with a salary of $1200 will be filled by Civil Service examination on February 6th and 7th.

THE Göttingen Academy of Sciences offers a prize of 1000 Marks for a mathematical paper to be submitted before the first of February 1901. The details can be obtained by addressing the Secretary.

THE world at large, and even many of those who are interested in the history of mechanical engineering, says the *Scientific American*, do not know that the body of the great engineer, Robert Fulton, lies in Trinity churchyard in New York City, being interred in the Livingston family vault. There is no mark or inscription to indicate its resting place. In view of the epoch-making character of the work of Fulton, and of his eminence as an engineer, and of his indomitable perseverance in the development of steam navigation in the face of the greatest obstacles, it has been deemed desirable that his tomb should be marked by a suitable monument. The Council of the American Society of Mechanical Engineers had the matter brought to its attention at the Washington meeting last May. The idea was warmly welcomed, and a committee was appointed to investigate the proper method of accomplishing the suitable marking of the grave. The committee has found its efforts heartily met both by the Trinity corporation and by members of the Fulton family. The Society has been assured that a suitable place will be provided in Trinity churchyard for such a monument as may be erected, and that the remains of Fulton will be removed to such a place when the monument is ready. The Society possesses a number of memorials of Robert Fulton, including furniture, his portrait by his own hand, drawings, autograph letters, and other personal relics. Indeed, it may be said that the Society is Fulton's literary heir. In view of this fact, the action of the Society is most dignified and fitting. A subscription is now being raised by it, and there is little question but that sufficient funds will be obtained to erect a most admirable memorial to mark the place where lies the body of one of the earliest and greatest of American engineers.

It is poetic justice that Fulton should continue to rest in the spot where he was interred. At the front of the quaint old burying ground run the cable cars, at the rear the electric cars and the elevated road, and at the foot of Rector Street, the other boundary, two of the fastest vessels on the bay make their landings. Almost across the street is one of the tallest buildings which has ever been erected, and Wall Street commences directly in front of the burying ground. What more fitting spot could be obtained for the resting place of one whose activities contributed in so large a degree to the progress which is so much in evidence immediately around the historic old church?

UNIVERSITY AND EDUCATIONAL NEWS.

THE University of Pennsylvania has received a gift of $250,000 from the estate of the late H. H. Houston, formerly a trustee and a generous benefactor of the University. Fifty thousand dollars is to be used for the dormitory system; the remaining $200,000 for such purposes as the trustees may desire.

PLANS have been filed for a new building for the Horace Mann School, the model school of Teachers College, Columbia University. The estimated cost is $350,000; the building will occupy the block on Broadway between 120th and 121st Street, adjoining the College.

O. H. INGHAM, of La Crosse, Wis., has given $15,000 toward the building of a new school of science for Ripon (Wis.) College.

THE new laboratories for bacteriology and pathological research at Mason University College, Birmingham, were opened on Wednesday, December 6th. Dr. E. Rickards gave £1,000 toward the equipment.

MSS. intended for publication and books, etc., intended for review should be sent to the responsible editor, Professor J. McKeen Cattell, Garrison-on-Hudson, N. Y.

*THE CENTURY'S PROGRESS IN APPLIED MATHEMATICS.**

I.

The honor of election to the presidency of the American Mathematical Society carries with it the difficult duty of preparing an address, which may be at once interesting and instructive to a majority of the membership, and which may indicate at the same time the lines along which progress may be expected in one or more branches of our favorite science. In partial recognition of the honor you have conferred upon me it has seemed that I could do no better than to consider with you some of the principal advances that have been made in mathematical science during the past century. But here at the outset one must needs feel sharply restricted by the limitations of his knowledge and by the wide extent of the domain to be surveyed. Especially must this be the case with one who belongs to no school of mathematicians, unless it be the 'old school' of inadequate opportunities and desultory training. On account of these conditions, I have found it essential to accept the ordinary division of the science into pure and applied mathematics and to confine my attention in this address wholly to applied mathematics. Here again, however, it is

* Address of the President of the American Mathematical Society, read December 28, 1899.

necessary to impose restrictions, for the domain thus divided is still far too large to be reviewed adequately in the brief interval allotted to the present occasion. I have therefore limited my considerations chiefly to those branches of applied mathematics which were already recognized as such at the beginning of the present century. The most important of these branches appear to be analytical mechanics, geodesy, dynamical astronomy, spherical or observational astronomy, the theory of elasticity, and hydromechanics. This rather arbitrary subdivision may be made to include several important branches not enumerated, while it must exclude others of equal or greater importance. Thus the theory of heat diffusion which led Fourier to the wonderful analysis which bears his name may be alluded to under physical geodesy; the theories of sound and light may be regarded as applications merely of the theories of elasticity and hydromechanics; while the theories of electricity, magnetism, and thermodynamics, which are the peculiar and perhaps most important developments of the present century, must be excluded almost altogether.

Another difficulty which besets one who would speak of the progress in question is that arising from the technicalities of the subjects to be discussed. Beautiful and important as these subjects are when arrayed in their mathematical dress, and thrilling as they truly are when rehearsed with appropriate terminology in the quiet of one's study, it must be confessed that they are on the whole rather uninviting for the purposes of semi-popular exposition. In order to meet this difficulty it seems best to relegate technicalities which demand expression in symbols to footnotes and, while freely using technical terminology, to translate it into the vernacular whenever essential. Thus it is hoped to avoid the dullness of undue condensation on the one hand, and the superficiality of mere literary description on the other.

The end of the last century marks one of the most important epochs in the history of mathematical science. This time, one hundred years ago, the master work of Lagrange (1736–1813), the Mécanique Analytique, had been published about eleven years. The first two volumes of the Mécanique Céleste of Laplace (1749–1827), undoubtedly the greatest systematic treatise ever published, had just been issued. Fourier (1768–1830), whose mathematical theory of heat was destined to play a wonderful rôle in pure and applied mathematics, was a soldier statesman in Egypt, where with Napoleon he stood before the pyramids while the centuries looked down upon them.* Gauss (1777–1855), who with Lagrange and Cauchy (1789–1857) must be ranked among the founders of modern pure mathematics, was a promising but little known student whose Disquisitiones Arithmeticae and other papers were soon to win him the directorship of the observatory at Göttingen. Poisson (1781–1840), to whom we owe in large part the beginnings of mathematical physics, had just started on his brilliant career as a student and professor in the École Polytechnique. Bessel (1784–1846), whose theories of observational astronomy and geodesy were destined soon to assume a prominence which they still hold, was an accountant in a trading house at Bremen. Dynamical astronomy, the favorite science of the day was under the dominating genius of Laplace, with no one to dispute his preëminence, and with only Lagrange and Poisson as friendly competitors in the same field. Rational mechanics as we now know it, was soon to

* The bombastic words of Bonaparte, "Songez que du haut de ces pyramides quarante siècles vous contemplent," may be excused, perhaps, in view of the fact that Fourier, Monge, and Berthollet were present on the occasion.

be simplified and systematized by Poinsot (1777–1859), Poisson, Möbius (1790–1868), and Coriolis (1792–1843), who were all at this time under twenty-five years of age. The undulatory theory of light, in which Young (1773–1829), Fresnel (1788–1827), Arago (1786–1853), and Green (1793–1841) were to be the most conspicuous early figures, was just beginning to be considered as an alternative to the emission theory of Newton. The theory of elasticity, or the theory of stress and strain as it is now called, was about to be reduced to the definiteness of formulas at the hands of Navier (1785–1836), Poisson, Cauchy, and Lamé (1795–1870). Planetary and sidereal astronomy, to which so much of talent, time, and treasure have since been devoted, was soon to receive the fruitful impetus imparted to it by the German school of Gauss, Bessel, Encke (1791–1865), and Hansen (1795–1874).

The advances that have been made during the past century in analytical mechanics must be measured from the elevated standard attained by Lagrange in his Mécanique Analytique. To work any improvement over this, to simplify its demonstrations, or to elaborate its details, was a task fit only for the keenest intellects. Lagrange had, as he supposed, reduced mechanics to pure mathematics. Geometrical reasonings and diagrammatic illustrations were triumphantly banished from this science and replaced by the systematic and unerring processes of algebra. "Ceux qui aiment l'Analyse," he says, "verront avec plaisir la Mécanique en devinir une nouvelle branche, et me sauront gré d'en avoir étendu ainsi le domaine." The mathematical world has not only accepted Lagrange's estimate of his work, but has gone further, and considers his achievement one of the most brilliant and important in the whole range of mathematical science. "The mechanics of Lagrange," as Mach has well said, "is a stupendous contribution to the economy of thought."*

Nevertheless, improvements were essential, and they came in due time. As we can now see without much difficulty, Lagrange and most of his contemporaries in their eagerness to put mechanics on a sound analytical basis overlooked to a serious extent its more important physical basis. The prevailing mathematical opinion was that a science is finished as soon as it is expressed in equations. One of the first to protest against this view was Poinsot, though the preëminent importance of the physical aspect of mechanics did not come to be adequately appreciated until the latter half of the present century. The animating idea of Poinsot was that in the study of mechanics one should be able to form a clear mental picture of the phenomena considered; and that it does not suffice to put the data and the hypotheses into the hopper of our mathematical mill and then to trust blindly to its perfection in grinding the grist. In elaborating this idea he produced two of the most important elementary treatises on mechanics of the century. These are his Éléments de Statique published in 1804, and his Théorie Nouvelle de la Rotation des Corps published in 1834.† In the former work he developed the beautiful and fruitful theory of couples and their composition, and the conditions of equilibrium, as they are now commonly expressed in elementary books.

*The Science of Mechanics, by Dr. Ernst Mach. Translated from the German by Thomas J. McCormack. Chicago, Open Court Publishing Co., 1893.

†Outlined to the Paris Academy in 1834. In the introduction to the edition of 1852 he says, "Voici une des questions qui m'ont le plus souvent occupé, et, si l'on me permet de parler ainsi, une des choses que j'ai le plus désiré de savoir en dynamique.

"Tout le monde se fait une idée claire du mouvement d'un point, * * * Mais, s'il s'agit du mouvement d'un corps de grandeur sensible et de figure quel-conque, il faut convenir qu'on ne s'en fait qu'une idée très-obscure."

In the latter he took up the more recondite question of rendering a clear account of the motion of a rigid body. This problem had been treated already by the illustrious Euler, d'Alembert, Lagrange, and Laplace, and it seemed little short of temerity to hope for any improvement. But Poinsot entertained that hope and his efforts proved surprisingly successful. His little volume of about one hundred and fifty pages is still one of the finest models of mathematical and mechanical exposition; and his repeated warning, "gardons-nous de croire qu'une science soit faite quand on l'a réduite à des formules analytiques," has been fully justified. He gave us what may be called the descriptive geometry of the kinetics of a rotating rigid body, the 'image sensible de cette rotation'; he clarified the theory of moments of inertia and principal axes; he made plain the meaning of what we now call the conservation of energy and the conservation of moment of momentum of systems which are started off impulsively; and he surpassed Laplace himself in expounding the theory of the invariable plane.

Another elementary work of prime importance in the progress of mechanics was Poisson's Traité de Mécanique. Poisson belonged to the Lagrangian school of analysts, but he was so profoundly devoted to mathematical physics that almost all his mathematical work was suggested by and directed towards practical applications. His facility and lucidity in exposition rendered all his works easy and attractive reading, and his treatise on mechanics is still one of the most instructive books on that subject. He was one of the first to call attention to the value of the principle of homogeneity in mechanics,* a principle which, as expanded in Fourier's theory of dimensions,† has proved of the greatest utility in the latter half of the century. The influence of Poisson's work in mechanics proper, very widely extended, of course, by his memoirs in all departments of mathematical physics, is seen along nearly every line of progress since the beginning of the century.

Of other works which paved the way to the present advanced state of mechanical science, it may suffice to mention the Cours de Mécanique* of Poncelet (1788–1867), the Traité de Mécanique des Corps Solides et de l'Effet des Machines† of Coriolis, and the Lehrbuch der Statik‡ of Möbius. To the two former of these authors we owe the fixation of ideas and terminology concerning the doctrine of mechanical work, while the suggestive treatise of Möbius foreshadowed a new type of mechanical concepts since cultivated by Hamilton (Sir W. R., 1805–1865). Grassmann (1809–1877), and others under the general designation of vector analysis.

Following close after the development of the elementary ideas whose history we have sketched came the important improvements in the Lagrangian analysis due to Hamilton.§ With these additions of Hamilton, amplified and clarified by the labors of Jacobi, Poisson, and others,|| analytical mechanics may be said to have reached its present degree of perfection so far as mathematical methods are concerned. By these methods every mechanical question may be stated in either of three characteristic though interconvertible ways, namely: by the equations of d'Alembert,

*See Article 23, Tome I., Traité de Mécanique, 2d ed., Paris, 1833.

† 'Théorie Analytique de la Chaleur,' Paris, 1822.

* Metz, 1826.

† Paris, 1829.

‡ Leipzig, 1837.

§ 'On a general method in dynamics.' *Philosophical Transactions*, 1834-35.

|| For an account of these additions and for a complete list of papers bearing on the subject (up to 1857), one should consult the admirable report of Cayley on 'Recent progress in dynamics,' published in the Report of the British Association for the Advancement of Science for 1857.

by the equations of Lagrange, and by the equation of Hamilton. Each way has special advantages for particular applications, and together they may be said to condense into the narrow space of a few printed lines the net results of more than twenty centuries of effort in the formulation of the phenomena of matter and motion.

Such was the state of mechanical science when the great physical discovery of the century, the law of conservation of energy, was made. To give adequate expression to this law it was only necessary to recur to the Mécanique Analytique, for herein Lagrange had prepared almost all of the needful machinery. So well indeed were the ideas and methods of Lagrange adapted to this purpose that they have not only furnished the points of departure for many of the most important discoveries* of the present half century, but they have also supplied the criteria by means of which mechanical phenomena in general are most easily and effectively defined and interpreted.

Of the special branches of analytical mechanics which have undergone development during this century, by far the most important is that known as the theory of the potential function. This function first appeared in mathematical analysis in a memoir of Lagrange in 1777 † as the expression of the perturbative function, or force function. It next appeared in 1782 ‡ in a memoir by Laplace. In this memoir Laplace's equation § appears for the first time, being here expressed in polar coördinates. In 1787* the same equation appears in the more usual form as expressed by rectangular coördinates.

Strange as it now seems when viewed by the light of this end of the century, nearly thirty years elapsed before Laplace's equation was generalized. Laplace had found only half of the truth, namely, that which applies to points external to the attracting masses.† Poisson discovered the other half in 1813.‡ Thus the honors attached to the introduction of this remarkable theorem are divided between them, and we now speak of the equation of Laplace and the equation of Poisson, though the equation of Poisson includes that of Laplace.

Next came the splendid contributions of George Green under the modest title of "An essay on the application of mathematical analysis to the theories of electricity and magnetism."§ It is in this essay that the term 'potential function' first occurs. Herein also his remarkable theorem in pure mathematics, since universally known as Green's theorem, and probably the most important instrument of investigation in the whole range of mathematical physics, made its appearance.

We are all now able to understand, in a general way at least, the importance of Green's work, and the progress made since the publication of his essay in 1828. But fully to appreciate his work and subsequent progress, one needs to know the outlook for the mathematico-physical sciences as it appeared to Green at this time, and to realize his refined sensitiveness in promulgating his discoveries.

*Especially those in the theories of electricity, magnetism, and thermodynamics.

‡ *Paris Memoires* for 1782, published in 1785.

§ $$\Delta^2 V = \frac{\partial^2 V}{\partial x^2} + \frac{\partial^2 V}{\partial y^2} + \frac{\partial^2 V}{\partial z^2} = 0.$$

$\Delta^2 V$ is called the Laplacian of V.

* *Paris Memoires* for 1787, published in 1789.

† That is, Laplace's equation is $\Delta^2 V = 0$, while Poisson's is $\Delta^2 V + 4\pi k\rho = 0$, V being the potential and ρ the density at the point (x, y, z), and k being the gravitation constant.

‡ Poisson's equation was derived in a paper published in *Nouveau Bulletin * * * Société Philomatique*, Paris, Dec., 1813.

§ Nottingham, 1828.

"It must certainly be regarded as a pleasing prospect to analysts," he says in his preface, "that at a time when astronomy from the state of perfection to which it has attained, leaves little room for further applications of their art, the rest of the physical sciences should show themselves daily more and more willing to submit to it. * * * Should the present essay tend in any way to facilitate the application of analysis to one of the most interesting of the physical sciences, the author will deem himself amply repaid for any labor he may have bestowed upon it; and it is hoped the difficulty of the subject will incline mathematicians to read this work with indulgence, more particularly when they are informed that it was written by a young man, who has been obliged to obtain the little knowledge he possesses, at such intervals and by such means, as other indispensable avocations which offer but few opportunities of mental improvement, afforded." Where in the history of science have we a finer instance of that sort of modesty which springs from a knowledge of things?

The completion of the potential theory, so far as it depends on the Newtonian law of the inverse square of the distance, must be credited to Gauss, though a host of writers has since contributed many valuable additions in the way of details. Early in the century Gauss had begun the study of the absorbing problems of the day, namely, problems of attractions and repulsions. The prevailing notion of mathematical physicists seems to have been that all mechanical phenomena may be attributed to attractions and repulsions between the ultimate particles of matter and the ultimate particles of 'fluids' associated with matter. The difficulties of action at a distance, without the aid of an intervening medium, happily, did not trouble them at that time; for who shall say that their labors would have been more fruitful if they had stopped to remove these difficulties? Gauss's first memoir in this field relates to the attractions of homogeneous ellipsoidal masses,* and dates from 1813. It was in this memoir that he published a number of the elegant theorems † which are now found in the elementary books on the theory of the potential function. In 1829 he published his theory of fluid figures in equilibrium,‡ and in 1832 there followed one of the most important papers of the century on the intensity of terrestrial magnetic force expressed in what we now call absolute units. § Six years later he published his wonderful theory of the earth's magnetism || and applied it to all existing observational data. This theory is a splendid application of the potential theory, and his entire investigation is one of the most beautiful and useful contributions to mathematical physics of the century. Well was he qualified, therefore, to complete the theory of the Newtonian potential function in the collection of theorems published in his memoir ¶ of

* 'Theoria attractionis corporum sphaeroidicorum ellipticorum homogeneorum,' 1813. See Gauss's Werke, Band V., Göttingen, 1877.

† Especially the theorem giving the values of the surface integral

$$\int \frac{\cos (s, n)}{s^2} dS,$$

where dS is an element of any closed surface, s the distance from dS to any fixed point, and n indicates the normal to the surface at dS. This gave the key to the very important theorem of the surface integral of the normal acceleration, or

$$\int \frac{\partial V}{\partial n} dS.$$

¶ 'Allegemine Lehrsätze in Beziehung auf die im verkehrten Verhältnisse das Quadrats der Entfernung wirkenden Anziehungs- und Abstossungs-Kräfte.' Werke, Band V.

1840. This is still the fundamental memoir on the subject of which it treats, and must be regarded as one of the most perfect models of mathematical exposition. In respect to clearness and elegance, indeed, the works of Gauss are unsurpassed. "In his hands," as Todhunter has said,* "Latin and German rival French itself for clearness and precision." "Alles gestaltet sich neu unter seinen Händen," was the tribute † of Bessel; and the lapse of two generations has served only to increase admiration for the genius and industry which made Gauss one of the most conspicuous figures in the science of the nineteenth century.

The importance of the theory of the potential function when considered in its historical aspects is found to consist not so much in the rich harvest of results it has afforded in the field of gravitation, as in its direct bearing on the developments of other branches of mathematical physics. For the points of view and the analytical methods of the Newtonian function have been adapted and extended with brilliant success to the interpretation of almost all kinds of mechanical phenomena. Thus it has come about that we have now to deal with many kinds of potential, as logarithmic potential, velocity potential, displacement potential, electric potential, magnetic potential, thermodynamic potential, etc., each of which bears a more or less close mathematical analogy to the Newtonian function.

In the closing paragraph of his Exposition du Système du Monde, Laplace refers to the immense progress made in astronomy since the geocentric theory was displaced by the heliocentric theory of the solar system. This progress is specially remarkable when we consider that it depended on the discovery, so humiliating to man, of the relatively insignificant dimensions and inconspicuous rôle of our planet. But we agree with Laplace that "Les resultats sublimes auxquels cette découverte l'a conduit sont bien propres à le consoler du rang qu'elle assigne à la Terre, en lui montrant sa propre grandeur dans l'extrême petitesse de la base qui lui a servi pour mesurer les cieux." All astronomy is based on a knowledge of the size, the shape and the mechanical properties of the earth; and it is not surprising, therefore, that a large share of the mathematical investigations of the century should have been directed to the science of geodesy. Founded in the middle of the last century by Clairaut* and his contemporaries; recast by Laplace and Legendre † (1752–1833) in the early part of this century; systematized and extended to a remarkable degree by the German geodesists, led especially by the incomparable Bessel;‡ this science has now come to occupy the leading position in point of perfection of methods and precision of results. So great, in fact, has been the growth of this science during the century that recent writers have found it desirable to subdivide the subject into two parts called mathematical geodesy and physical geodesy respectively, though both parts are nothing if not mathematical.§

In a former address I have considered somewhat in detail certain of the more

* History of the Theories of Attraction and Figure of the Earth, Vol. II., p. 235.

† In a letter to Olbers, 1818.

* Clairaut's work, Théorie de la Figure de la Terre, Paris, 1743, was the pioneer work in physical geodesy.

† The name of Legendre is famous in geodesy by reason of his beautiful theorem which makes the solution of a geodetic triangle almost as easy as the solution of a plane triangle.

‡ Bessel's contributions to astronomy and geodesy are collected in Abhandlungen von F. W. Bessel, herausgegeben von Rudolf Engelmann, in drei Bänden, Leipzig, Wilhelm Engelmann, 1875.

§ See, for example, Die Mathematischen und Physikalischen Theorieen der Höheren Geodäsie von Dr. F. R. Helmert, Leipzig, B. G. Teubner, Teil I., 1880; Teil II., 1884.

salient mathematical problems which have arisen in the study of the earth;* and the present review may hence be restricted to a rapid résumé of the less salient but perhaps more recondite problems, and to the briefest mention of problems already discussed.

Adopting the convenient nomenclature of geologists, we may consider the earth as made up of four parts, namely, the atmosphere; the hydrosphere, the oceans; the lithosphere, or crust, and the nucleus. Beginning with the first of these we are at once struck by the fact that much greater progress has been made during the century in the investigation of the kinetic phenomena of the atmosphere than in the study of what may be called its static properties. Evidently, of course, the phenomena of meteorology are essentially kinetic, but it would seem that the questions of pressure, temperature and mass distribution of the atmosphere ought to be determined with a close approximation from purely statical considerations. This appears to have been the view of Laplace, who was the first to bring adequate knowledge to bear upon such questions. He investigated the terrestrial atmosphere as one might investigate the gaseous envelope of an unilluminated planet.† He reached the conclusion that the atmosphere is limited by a lenticular-shaped surface of revolution whose polar and equatorial diameters are about 4.4 and 6.6 times the diameter of the earth respectively, and whose volume is about 155 times that of the earth.‡ If this conclusion be true our atmosphere should reach out to a distance of about 26,000 miles at the equator and to a distance of about 17,000 miles at the poles. It does not appear, however, that Laplace attempted to assign the distribution of pressure and density, and hence total mass of the atmosphere within this envelope; and I am not aware that any subsequent investigator has published a satisfactory solution of this apparently simple problem.*

*On the Mathematical Theories of the Earth. Vice-presidential address before Section of Astronomy and Mathematics of the American Association for the Advancement of Science, 1889. *Proceedings of A. A. A. S.*, for 1889.

† Mécanique Céleste, Livre III., Chap. VII., and Livre X., Chapts. I.–IV.

‡ Laplace's equation to a meridian section of this envelope is

$$x^{-1} - x_0^{-1} + \tfrac{1}{2}ax^2\cos^2\phi = 0,$$

where $x = r/a$, r being the radius vector measured from the center of the earth and a the mean radius of the earth; a is the ratio of centrifugal to gravitational acceleration at the equator of the earth; ϕ is geocentric latitude, and x_0 is the value of x for $\phi = \pi/2$.

The problem of the statical properties of the atmosphere may be stated in three equations, namely:

$$\Delta^2 V + 4\pi k\rho - 2\omega^2 = 0,$$
$$dp = \rho dV,$$
$$p = f(\rho, \tau).$$

In these V is the potential at any point of the atmosphere; p, ρ, τ being the pressure, density and temperature at the same point; k is the gravitation constant; and ω is the angular velocity of the earth. The above equation of Laplace neglects the mass of the atmosphere in comparison with the mass of the rest of the earth. An essential difficulty of the problem lies in the unknown form of the function $f(\rho, \tau)$.

*I have sought a solution with a view especially to determine the mass of atmosphere. A class of solutions satisfying the mechanical conditions of the following assumptions has been worked out. Thus, assuming $p = c\rho^m$, which includes the adiabatic relation, $p = c\rho^{1.41}$, and the famous Laplacian relation, $\partial p/\partial\rho = 2c\rho$; and the law of Charles and Gay-Lussac, $p = C\rho\tau$; there results

$$\frac{p}{p_0} = \left(\frac{Q}{Q_0}\right)^{\frac{m}{m-1}}, \quad \frac{\rho}{\rho_0} = \left(\frac{Q}{Q_0}\right)^{\frac{1}{m-1}}, \quad \frac{\tau}{\tau_0} = \frac{Q}{Q_0},$$

where $Q = x^{-1} - x_0^{-1} + \tfrac{1}{2}ax^2\cos^2\varphi$

defined above; Q_0 is the value of Q for $x = 1$ and $\phi = \pi/2$; and p_0, ρ_0, τ_0 are the values of p, ρ, τ at the same point $(x = 1, \phi = \pi/2)$.

Using the adiabatic law the above formula for ρ leads to a mass for the atmosphere of about 1/1200th of the entire mass of the earth. But since the adiabatic law gives too low a pressure, density and temperature gradient, this can only be regarded as an upper limit to the mass of the atmosphere. A lower limit of about 1/1000000th of the earth's mass is found by assuming that the mass of the atmosphere is equal to the mass of water or mercury which would give an equivalent pressure at the earth's surface.

On the other hand, the general character of the circulation of the atmosphere and the meteorological consequences thereof, have been brought within the domain of mathematical research, if they have not yet been wholly reduced to quantitative precision. The pioneer in this work was a fellow-countryman, William Ferrel (1817–1891),* who, like Green, came near being lost to science through the obscurity of his early environment. It is a curious though lamentable circumstance, illustrating at once the peculiar shyness of Ferrel and the proverbial popular indifference to discoveries which cannot be patented, that a man who had mastered the Principia and the Mécanique Céleste and who had laid the foundation of our theory of the circulation of the atmosphere, should have found no better medium for the publication of his researches than the semi-popular columns of a journal devoted to medicine and surgery. But such was the medium through which Ferrel's 'Essay on the Winds and Currents of the Ocean' appeared † in 1856. Since that time notable progress has been made at the hands of Ferrel, Helmholtz (1821–1894), Oberbeck, Bezold and others ;‡ so that we may entertain the hope that the apparently erratic phenomena of the weather will presently yield to mathematical expression, just as the similar phenomena of oceanic tides and terrestrial magnetism have already yielded to the power of harmonic analysis.

* For a biography and autobiographical sketch of Ferrel, and a list of his publications, see Biographical Memoirs of the National Academy of Sciences, Vol. III., pp. 265–309. Washington, 1895.

† In *Nashville Journal of Medicine and Surgery*, Oct. and Nov., 1856.

‡ Some of the most important papers and memoirs on this subject, collected and translated by Professor Cleveland Abbe, have been published by the Smithsonian Institution under the title 'The Mechanics of the Atmosphere.' Smithsonian Miscellaneous Collections, No. 843, Washington, 1891.

When we pass from the atmosphere to the hydrosphere, several questions concerning the nature and properties of their common surface, or what is usually called the sea surface, immediately demand attention. The most important of these are what may be distinguished as the static and the kinetic phenomena of the sea surface. Since tidal oscillations belong more properly to hydrokinetics, we may here confine attention to the static phenomena.

Starting from the datum plane fixed by Laplace, the most important contribution to the theory of physical geodesy since his time is the remarkable memoir of Sir George Gabriel Stokes 'On the Variation of Gravity at the Surface of the Earth.'* Adopting the hypothesis of original fluidity, or the more general hypothesis of a symmetrical arrangement of the strata of the earth, with increasing density towards the center, Laplace had shown that the acceleration of gravity in passing from the equator to the poles should increase as the square of the sine of the latitude.† This conclusion agreed well with the facts of observation; and Laplace rested content in the opinion that his hypothesis was verified. But Stokes showed that the law of variation of the acceleration of gravity at the surface of the sea is wholly determined by that surface, regardless of the mode of distribution of the earth's mass. This, as we now see, of course, is a direct result of the theory of the potential function; for the sea surface is an equipotential surface, and since it is observed to be closely spheroidal, the formula of Laplace follows independently of all hypothesis save that of the law of gravitation. But while Laplace's formula

* Read April, 1849. See Mathematical and Physical Papers by G. G. Stokes, Cambridge University Press, 1883, Vol. II.

† Laplace's formula is $g = \alpha + \beta \sin^2\phi$, where α is the value of g at the equator, β is a constant, and ϕ is the latitude of the place.

and the arguments by which he reached it throw no light on the distribution of the earth's mass, a slight extension of his methods gives a formula which shows that any considerable difference in the equatorial moments of inertia of the earth would produce a variation in the acceleration of gravity dependent on the longitude of the place of observation.* Thus it is possible by means of pendulum observations alone to reach the conclusion that the mass of the earth is very nearly symmetrically distributed with respect to its equator and with respect to its axis of revolution.

A question of great interest with which the acceleration of gravity at the sea surface is closely connected is that of the earth's mass as a whole. About two years ago I published a short paper which gives the product of the mean density of the earth and the gravitation constant in terms of the coefficients of Laplace's formula and the dimensions of the earth.† It was shown that this product can be easily computed from existing data to five significant figures with an uncertainty of only one or two units in the last figure; thus making it possible to obtain the mass of the earth to a like degree of precision if the constant of gravitation can be equally well determined. In a subsequent communication to this Society it was explained that the product in question is equal to 3π divided by the square of the periodic time of an infinitesimal satellite which would pass around the earth just grazing the equator if there were no atmosphere to impede its progress. The periodic time of such a satellite would be 1 hour, 24 minutes, 20.9 seconds. Attention is called to this subject with the hope that some mathematician may point out another possible relation between the gravitation constant and the mean density of the earth which can be accurately observed, or that some physicist may show how the gravitation constant can be measured directly with a precision extending to five significant figures.

The lithosphere is the special province of the geologist, and we may hence pass on to the nucleus, or chief part of the mass of the earth. Much time and attention have been devoted to the study of the important but intricate problems which the geometers of the early part of the century left to their successors. But while the obscurities and vagaries of our predecessors have been cleared away, it must be confessed that our improved mathematical apparatus has not brought us very far ahead of the positions of Laplace and Fourier as regards the constitution and properties of the nucleus. With respect to the law of the distribution of density in the nucleus it may be said that although Laplace's law* is probably not ex-

* See Helmert, Geodäsie, Band II., p. 74. The expression for the acceleration is

$$g = \alpha + \beta \sin^2 \phi + \gamma \cos^2 \phi \cos 2\lambda,$$

where α, β, γ are constants, and ϕ, λ are latitude and longitude respectively; and the constant γ involves the difference of the equatorial moments of inertia as a factor.

† See *The Astronomical Journal*, No. 424. This product is expressed thus:

$$k\rho = \frac{2\pi}{T^2} + \frac{3(\alpha s_1 + \beta s_2)}{4\pi a \sqrt{1 - e^2}};$$

wherein k is the gravitation constant, ρ is the mean density of the earth, T is the number of mean solor seconds in a sidereal day, α and β are the first two constants in the formula $g = \alpha + \beta \sin^2 \phi + \gamma \cos^2 \phi \cos 2\lambda$ for the acceleration of gravity at the sea surface in latitude φ and longitude λ; a is the half major axis and e is the eccentricity of the earth's spheroid; and

$$s_1 = \frac{1}{2}\left\{1 + \frac{1 - e^2}{2e} \log \frac{1 + e}{1 - e}\right\},$$

$$s_2 = \frac{1 - e^2}{4e^2}\left\{\frac{2e}{1 - e^2} + \log \frac{1 - e}{1 + e}\right\}.$$

The resulting numerical value is

$$k\rho = 36797 \times 10^{-11}/(\text{second})^2.$$

* The Laplacian distribution of pressure, density, and potential in the earth are defined essentially (neglecting the effect of rotation) by the three following equations:

act it is yet quite as nearly correct as our observed information requires.*

COLUMBIA UNIVERSITY.

(*To be concluded.*)

THE POSITION THAT UNIVERSITIES SHOULD TAKE IN REGARD TO INVESTIGATION.†

WHAT position shall universities take with regard to investigation? When the honor was done me of asking me to take part in this discussion, my first thought, after the sensation of complacency at the compliment, was that there could hardly be a *discussion* where all held probably very nearly the same views, and that the great difficulty would be to say anything that would not be better said by another. Then as I began to think more carefully, I saw that the question was not, as I had at first imagined it to be, "what shall universities do to encourage those on their staffs to investigate?" It is far wider than that. It comprises a whole group of questions concerning which there may be every shade of opinion. So the more I thought, the more I admired the wisdom the committee had shown in their choice of a subject. Later still, it dawned upon me that surely it is a most satisfactory sign of progress that this Society should meet to discuss such a subject, with the conviction that, though without the shadow of a legal right to make claims, we are, nevertheless, sure of a sympathetic hearing from both universities and the public.

First of all let us consider the place of investigation in education, as a means of mental training, quite apart from any definite results. Surely this alone opens a wide field for one afternoon's ramble, in which there are diverging and recrossing paths enough to furnish us the surprises of unexpected partings and unhoped-for reunions.

I would here remark that perhaps some confusion is possible from different interpretations of the word 'investigation.' According to some it means simply practical work, object teaching, or, better still, object study. According to others it is the search for something new. With regard to the value of the former we are all pretty well agreed. We do not need to be told what an advance it is over the old way of learning the statements of others concerning matters well within the sphere of observation. It may sometimes be carried too far, but in view of its great usefulness we will not quarrel with a little abuse. With what is meant by the second interpretation the case is different. Excepting some singularly gifted natures, it does not, in my opinion, concern the student. The universal or even the very general application of this method is the result of an extreme reaction. It rests on a fallacy. Because investigation is a good thing, and worthy of encouragement, which all must admit, it is assumed to be good for all, and an accepted method of education, which conclusion I cannot adopt. It is for the beginner to learn what is worth learning in his particular field first of all. It is not easy in these days to learn all that is worth learning even in a very restricted department. To start on investigation with this only half-learned is a direct

$$\Delta^2 V + 4\pi k\rho = 0,$$
$$dp = \rho\, dV,$$
$$\frac{\partial p}{\partial \rho} = c\rho\,;$$

where p, ρ, V are the pressure, density, and potential at any point of the mass, k is the gravitation constant, and c is a constant securing the equality of the members of the last equation.

* With regard to what constitutes an adequate theory in any case, see an instructive paper by Dr. G. Johnstone Stoney on 'The kinetic theory of gas, regarded as illustrating nature.' *Proceedings, Royal Dublin Society*, Vol. VIII. (N. S.), Part IV., No. 45.

† Discussion before the American Society of Naturalists at the New Haven Meeting, December 25, 1899

injury to the student, whom it turns to premature specialization. It is both foolish and cruel to exact investigation as a part of the regular training of every student, and very unjust to imply that those whose taste does not lie that way are mentally inferior to those who dabble in research, no matter how ineffectively. It may be replied that, granting this, still it is a good and necessary training for those who in after life are to become investigators. I incline to dissent still, for the born investigator (and no other is worth much trouble) no more needs encouragement to investigate than the fish does to swim. I would, if anything, restrain him till his education has become broad and his mind mature. He will very quickly more than make up the lost time. Then let him have every encouragement.

As regards education I speak as a professor in a medical school, whose career has been so placed that he has seen this school develop into a department of a university. I feel that, in common with others, it has reached a point when it is in danger from the side of its scientific friends who mistake or will not learn the true purpose of a medical school. I so rarely find myself in complete accord with Huxley, that I cannot forbear, though it is not for the first time, quoting his deliberate opinion, that whoever adds one tittle that is unnecessary to medical education is guilty of a very grave offense. If this be true, as I firmly believe it is, we must look to it that the candidate for the degree of M.D. be not robbed of his time, none too long for learning medicine as an art, by specially conducted excursions into abstract science. It may be said, and said truly, that without such auxiliaries the education of the student wants something of the breadth which his should have who aspires to stand on the pinnacle; but this only emphasizes the fact, now becoming daily clearer, that there has grown up the need of what may be called advanced medicine. Some would have this strictly post-graduate, but it is probably wiser to have a difference in the course. On the one hand there is the young man who aspires to be a conscientious every-day practitioner of medicine, looking forward to a life of hard work among suffering humanity. Such a one is not to be refused the degree of an honored university, and told superciliously to go to the little school round the corner. Neither is he who, looking at the matter more as a scholar, desires through his studies to train himself to teach others and to widen the horizon of knowledge, to be told that we have no help to offer to one of his ideals. We must provide for both; but with what power I have I shall always protest against sacrificing the first to the second, though the latter is the one with whom my tastes incline me to sympathize.

To sum up thus far, I conclude that it is not the duty of universities to urge, still less to force, original investigation upon students. It should be at hand for those whose zeal is so great that it will take no denial.

The next question is what universities should do for research in the community at large. Are more prizes and scholarships to be offered? As to prizes I should hesitate to say yes. It is not well that they should be too common; but of scholarships for deserving men we can hardly have too many. It is most desirable that the universities should award them. They cannot, indeed, give the funds, but, these being provided, committees from the universities should give their time, care and experience to their proper administration. This is a most beneficent and dignified attitude for a university, midway between the generous donor and the deserving student, to see that the generosity of the former is neither neglected nor abused.

The next and last aspect of the question that I shall consider is "what shall a university do for the support and encouragement of investigators within its walls?" The primary function, in my opinion, of a professor is to teach; but, with certain exceptions of rare merit, it is necessary for his reputation and influence that he should do original work. The first duty of the university to him is that he should not be overburdened with teaching. The next problem is, how the expenses of his work are to be met. These must vary with the department. For some lines of research distant expeditions are requisite, necessarily so costly that they can hardly be provided for otherwise than by national or private munificence. But putting these aside, and speaking more particularly of biological and morphological work, the problem reduces itself to this: what help shall the university give to the investigator, (1) in the matter of providing the material, namely, the subject matter for the study, (2) the machinery and reagents for the work, (3) the means of illustrating it, and finally of publishing the paper. The last need is not urgent on account of the great number of journals of all kinds, but it exists in isolated cases. Till comparatively recently the position of universities has been much like that of the Pickwick Club, which when sending its honored founder and his companions on their travels saw no objection to every member paying his own bills. But professors for the most part suffer from 'that perpetual lack of pence which vexes public men,' and those who are not yet professors are, of course, vexed the more. Is it fair that a serious tax, ever increasing in direct ratio to his merit, should be laid on the investigator, especially as the university profits in no small degree by his success? I am sure we shall all agree it is not. But then difficulties present themselves as to how this help is to be given and distributed, assuming that the university admits the claim. Who are to be the chief beneficiaries? The most distinguished or the most needy? The oldest because of his years? Or the youngest because of his youth? And again is it just that the university should furnish large sums for bringing out papers of unknown merit? It seems to me that the most feasible way, if the money can be procured, is to place a sum in the hands of the professor at the head of each scientific department, to be spent for the good of that department, including publication, according to his discretion, or his lack of it. Should the latter be painfully apparent, the resulting unpopularity will surely be irresistible, and thus there will be a check on a system which may at first seem too arbitrary.

THOMAS DWIGHT.
HARVARD MEDICAL SCHOOL,
CAMBRIDGE, MASS.

THE primary function of a university is the diffusion of knowledge, and it is, I believe, equally true that these higher institutions of learning are in great part responsible for the extent to which knowledge is spread throughout the land. Before there can be diffusion of knowledge, however, there must be acquisition of knowledge, and we may at once ask the question, how far shall the university lend its aid in the encouragement of scientific research with a view to the enlargement of the boundaries of human knowledge? It is obvious that the force and energy of a great university must of necessity be given to the training of its students in the various departments of study laid down in the curriculum, and a university worthy of the name certainly cannot afford to devote the major part of its energies to the pursuit of scientific research, neither in my judgment would it be justified in so doing. By such a procedure, it would forfeit the right to the name of university, and its power for usefulness would be curtailed in no small measure

It is clear that loss in one direction might be counterbalanced by gain in another, but the true university must ever remain a place where the student can obtain knowledge of past discoveries, and of the sciences based thereon, together with that broad training which helps to make the educated man. In other words, the university cannot escape from its responsibility as an educational center for the diffusion of knowledge, and any attempt to transform the university into an institution for research alone would be detrimental to the best interests of higher education.

Shall the university, on the other hand, limit itself to routine instruction? To this there can be but one answer, and that is most emphatically, no. The true teacher of science, for example, must ever be a student, not only familiar with the past, but ever on the alert to interpret such signs as nature may make, quick to seize the opportunity to add to man's knowledge, to broaden and extend the limits of his chosen science, to keep in touch with the advances of the present and to harmonize these advances with the knowledge of the past, bearing clearly in mind that whatever is gained by scientific inquiry or research is never lost. As Sir Michael Foster has well said in a recent address, "what is gained by scientific inquiry is gained forever; it may be added to, it may seem to be covered up, but it can never be taken away."

The teacher of science who is content to devote himself entirely to the exposition of that which is known will never make an ideal teacher. He can never hope to arouse that enthusiasm among his students which comes from the man who adds to his power of teaching that love for his science and its advancement which prompts to steady, courageous application in the unravelling of nature's secrets. This influence for good upon the man himself is not to be overlooked, for I take it that the university has a selfish interest, if no other, in the intellectual development and advancement of the teacher who presides over this or that department of science. The pursuit of scientific inquiry, under proper conditions, tends to the development of moral courage and steadfast endurance; it is a school of discipline which leads to the acquisition of strength and power, which helps to make a man master of himself and at the same time obedient to nature's ways. As Professor Foster has said, men of science, though in themselves no stronger or better than other men, "possess a strength which is not their own, but is that of the science whose servants they are. Even in his apprenticeship the scientific inquirer, while learning what has been done before his time, if he learns it aright, so learns it that what is known may serve him not only as a vantage ground whence to push off into the unknown, but also as a compass to guide him in his course. And when fitted for his work he enters on inquiry itself, what a zealous, anxious guide, what a strict, and, because strict, helpful schoolmistress does nature make herself to him! Under her care every inquiry, whether it bring the inquirer to a happy issue or seem to end in nought, trains him for the next effort. She so orders her ways that each act of obedience to her makes the next act easier for him, and step by step she leads him on toward that perfect obedience which is complete mastery. Indeed, when we reflect on the potency of the discipline of scientific inquiry, we cease to wonder at the progress of scientific knowledge."

May we not, therefore, claim, from this standpoint alone, that the university should look with favorable eye upon scientific investigation within its boundaries, since its encouragement must lead to the development of strength and power in its teachers? Indeed, may we not urge that this recognition of the indirect advantages of scientific research to the university should give way to direct and positive encouragement, an encouragement which should manifest itself in such an allotment of routine duties as would afford a reasonable amount of time for research to all suitable teachers in the university? I say *suitable* teachers, and, speaking as a physiologist, I should like to raise the question, whether the teacher of an experimental science, like physiology, if he is truly a suitable teacher, must not be an investigator also. Do not the two of necessity go together? And must not the university, if at all zealous for the character of the instruction offered within its walls, see to it that its teachers of science are not merely adepts at expounding that which is known, but are equally ambitious to open up new paths of knowledge in their respective departments of science?

Another, and more direct, reason why the university should encourage and aid scientific investigation is that by so doing it enlarges its own scope of usefulness as an educational center. The modern university, if it is to fulfill its purpose as an educational institution, must be well equipped with laboratories and those other facilities which go to make the teaching of an experimental science a success. What would the teaching of physiology and physiological chemistry, even in elementary form, amount to without the aid of laboratory facilities? The university, whether it looks with a favoring eye upon investigation or not, must have ample appliances for the teaching of the experimental sciences, and the more complete the equipment the better adapted is the university for carrying on its legitimate work. Moreover, the university of to-day is called upon to provide instruction for more advanced students; men and women who are themselves looking forward to the possibility of becoming teachers, who are anxious to learn the methods of scientific work, and who are desirous of demonstrating for themselves experimentally the facts upon which the important theories and hypotheses of their chosen science depend. For the realization of proper instruction in these respects, the university must provide suitable equipment if it is to live up to its high privileges, as well as have a suitable corps of instructors capable of leading on such advanced workers. The university must, therefore, have at hand all those appliances which are essential for research or investigation, and which the individual worker can rarely afford. Why should not these be utilized by competent investigators for scientific research? Fine laboratories and fine apparatus are of value only so far as they contribute to the spread of knowledge, and if they can be utilized for the acquisition of new facts, so much greater will be their usefulness, and so much more credit to the university that renders them available. But, having the appliances, should not the university make strenuous efforts even to encourage research; not passive encouragement, but direct, positive encouragement, that will not rest until the laboratory is filled with earnest workers taking advantage of the various facilities provided? I think, yes, and it takes very little imagination to picture the direct and indirect advantages accruing both to the university and to science by the fulfillment of such a suggestion.

Contrast, as you easily can, the difference in the atmosphere between a physiological laboratory, for example, occupied solely by a class at stated intervals on certain days of the week, and the laboratory in which zealous workers are to be found, ever experimenting on new problems, spurred on continuously by the stimulating influence of new facts and new observations, making a rallying place for the earnest thinkers and workers who constitute an ever-present example for the elementary workers in the science. Who can measure the influence for good which emanates from such a laboratory? Does not the university derive, both directly and indirectly, an inestimable advantage from such surroundings, and may we not justly claim that the university by such encouragement of research adds directly to its own power and strength, while at the same time aiding in the advancement of the science? Its scope of usefulness is thereby greatly enlarged; advanced workers in the science are attracted to the university, and even the routine instruction given to the various classes, both graduate and undergraduate, is influenced by the atmosphere of earnest endeavor which permeates the laboratory. The tone of the institution is raised, while both student and instructor feel the stimulating effects of that environment which permits the carrying out of successful scientific work.

Granting all this, the question may be asked, how *far* is it allowable for the university to extend aid in the encouragement of research? It seems to me that the answer to this question must depend upon the resources of the individual institutions. The university must be true to the primary object of its existence. It cannot overlook the fact that it was created for a specific purpose, and the fulfillment of that purpose must be its first care. All higher institutions of learning, however, are bound to recognize the necessity of providing means for the carrying on of original investigations in the various branches of science. I believe, as a rule, it is better for our scientific workers to be connected with the university, than to carry on their work in connection with a special research laboratory, with complete freedom from academic duties. I think higher education would suffer if research work was limited to special research laboratories, and the advancement of science would not be as rapid as under existing conditions, where the research worker must spend a portion of his time in careful retrospect. Just as work in investigation helps to make a better teacher, so, in my judgment, the necessity of giving instruction to a body of young workers helps to make a better investigator. It should be the duty of the university, however, so far as possible, to allow time and provide means for investigation, and by the aid of scholarships and fellowships, judiciously awarded, offer inducements for the younger workers to spend a portion of their time in scientific research.

Do not the results which have been obtained by scientific workers in connection with our own and foreign universities afford ample proof of the value of this method of encouraging investigation and advancing scientific knowledge? Consider, if you will, the results which have been attained during the last twenty years in physiology; the advancement made along so many lines and in so many different directions, and then glance at the names of the men who have carried out these investigations and note their positions in life. They are practically all university men; men who have carried on research work in connection with their academic duties, in some cases unaided, but frequently with the coöperation of younger workers, assistants, fellows, etc., to whom they have taught in this way the methods of scientific investigation. I have just received the Jahresbericht für Thierchemie for 1898, containing the record of investigation for that year in physiological chemistry. The book contains 850 pages filled with brief abstracts of the researches in this somewhat narrow field of investigation. Does not this record indicate that investigation is being encouraged? That the universities and other institutions of learning are consciously or unconsciously taking a position of helpfulness toward scientific research? I believe this to be the case, and while we must admit that in this country there is not quite the same liberality as exists abroad, yet I believe that all of our more prominent institutions of learning are willing and anxious, so far as their means will allow, to foster the spirit of investigation, both for the personal advantage to be derived therefrom, and for the sake of advancing the knowledge of science in its various departments. Certainly, the university cannot afford to take any position other than that of helpfulness towards scientific research, or manifest any disposition other than one of coöperation in the attempts that are made to advance the boundaries of human knowledge.

R. H. CHITTENDEN.
YALE UNIVERSITY.

EDUCATION as a preparation for conduct involves a fitting in respect to the two all-important factors by which conduct is determined. The educated man differentiates himself from the uneducated by the greater range and variety and by the intrinsic character of the influences to which he is responsive, and again by his mode of response to these influences and to the ordinary and extraordinary events and situations which our common environment presents. The receptive side of education is the more tangible and therefore apt to absorb attention beyond its due. It is so obviously important—especially in days like these, when there is such an endless series of things which it is necessary and useful to know—to furnish the individual with the maximum opportunities of acquiring information, that the problem that is apt to be relatively neglected is that of fitting him to use what he acquires, of making his stock of knowledge not a burden to be carried, but part of the strength that carries.

In the realm of education action and reaction are not necessarily equal; the individual may be exposed to wholesome and inspiring influences and yet derive from them neither health nor strength. A thorough education includes a training in both action and reaction; it educates one to be widely and deeply and yet critically receptive, to be judiciously and ably and yet creatively expressive. From the first to the last it considers both these aspects; feeling and knowing, observing and assimilating must step by step be complemented by doing and experimenting, by coördinating and originating. However true that the response presupposes the stimulus, yet the latter alone in the complicated conditions here pertinent will not produce it; it requires a strengthening of the reaction impulse, a guidance of the executive capacities.

To indicate the application of this principle to the elementary and intermediate phases of education is no part of the present discussion; and yet it may be in place to record my conviction that the furtherance of the responsive and originative functions in these stages of education is itself an important aid to the proper recognition of the place of investigation in the university. If from kindergarten to common school, and from these to high school and college, coördinative thinking could be successfully taught, if each step of knowledge could be made to yield an increase in the capacity to handle and arrange one's thoughts, then the necessity of keeping aglow the flames thus kindled, of laying stress upon originality and achievement in the university would more easily gain due recognition.

It is apparent that I claim as an important function of investigative work in the university its directive influence upon collegiate and university studies; and the recognition of this function on the part of the university authorities must always be a prominent motive for the proper provision of opportunities for investigation. From whatever other points of view it may be or become the duty of the leading institutions of learning to contribute to the advancement of the boundaries of knowledge, the pedagogical motive will never lose its pertinence. But whether for the strengthening of its internal educational structure, or as a proper expansion of the university sphere of influence, there will always remain a close community of method and interest in all provision for research. That community is the furtherance of the investigative spirit. Fruitful investigation flourishes only in a proper soil and blossoms profusely only in a congenial atmosphere. One cannot have investigation without investigators; in some directions money may provide the materials, for the lack of which investigation must go halting, but in all directions investigators must be both born and trained. The inspiring intellectual life of our foremost universities certainly offers a most congenial atmosphere for the growth of that investigative spirit; the furtherance of that spirit is an indispensable factor in a worthy national and cultural progress.

It thus becomes not a supplementary duty but the very purpose of the university to provide an environment so thoroughly suited to the growth of investigation that it cannot but become its natural habitat. Research is indispensable to a university. says President Eliot, "because a university which is not a place of research will not long continue to be a good place of teaching; and, secondly, because this incessant, quiet, single-minded search after new truth is the condition of both material and intellectual progress for the nation and for the race."

It will be well to examine somewhat more closely the two aspects of investigation which I have selected for special emphasis —investigation for training and investigation for discovery. The working ideal of American universities is to provide their students with the maximum opportunities and privileges of which their degree of maturity and responsibility enables them to profit; and at the same time we continue the guidance of their progress in ever more indirect but no less efficient manner, until they strike out confidently, and as a rule creditably, in their chosen walks of life. We have not been tempted to imitate the German system which makes the passage from gymnasium to university an abrupt change from set tasks and stringent discipline to complete liberty with little guidance and no control. While it is proper that conventional ceremonies and new privileges should add zest to the assumption of the toga virilis, it is not proper that mistakes should be encouraged, nor that, for lack of a gradual transition, time and energy and strength should go astray. Men and women should have the liberty of making mistakes; there is a very real danger in over-guidance as well as in license. But the golden mean between these, though a narrow path, is broad enough to be readily found.

In the ideal which American universities attempt to realize, there are to be guide-posts enough to give the young explorer a confident feeling that others have trod the path before him, and to prevent useless wanderings into by-paths and *culs-de-sac*, and yet not enough to take away the incentive of independence and adventure, nor to lose the slightest opportunity to foster self-reliance and courage. It is necessary to understand this ideal and the consequent attitude of both guide and guided to appreciate the function in the university of investigation for training. For it seems to me that no other aspect of university studies can so readily be adapted to this ideal as the investigative aspect. I mean by this not merely the one topic that forms the basis of a thesis (which in the nature of things must often be quite detailed and not comprehensively significant);

but also the research attitude of the seminary, the participation in the problems of fellow-workers in the laboratory and study, the preparation for lectures and demonstrations, the presentation of technical material before clubs and societies, the critical digest of current contributions to learning and the tentative but stimulating first steps in productive authorship. In all these activities the attitude of the student is participative and expressive; not only absorbent but responsive; he must do and dare, he must count and weigh, he must thrust and parry; he is no longer wholly a spectator nor an auditor, he has a part, though a minor one, on the stage; and even the acquaintance with *the scene-painting* and *stage-carpentering* is a useful one for the training of the actor. It is in the special adaptation of investigation to accomplish these ends, to round out the motor side of education, that I see its pedagogical value. Research under judicious guidance is a training in coördination, a training in self-reliance, a training in readiness and resource, a training in reserve and critical ability, a training in construction and expression. It gives zest and dignity to what might otherwise seem to be insipid drudgery; by presenting conditions which must be met as best one can, investigation becomes a stern discourager of hesitancy; by its constant reference to and dependence upon the errors and outgrown opinions of the past, it is a wise encourager of caution and foresight. It teaches both how to look and how to leap. It maketh the full, and the ready, and the exact man. It would be unwise to forget that other aspects of university studies and university life contribute an essential quantum to the furtherance of the same qualities; but considering it with reference to its fitness in a systematic course of higher education, to elicit the full whole-souled response of ambitious youth, and in requiring just that proper measure of guidance and independence suitable to the capacities and purposes of university students, the position of investigation for mental training and discipline cannot hold a subordinate place.

Regarding investigation for discovery, I desire only to touch upon one or two aspects of it which are not so commonly associated with the term as they should be. While there is something to be said—in many departments much to be said—for investigation as a prudent and practical investment, there is no danger in a commercial democracy that this will remain unsaid. It is only in its relations to its constituency that it becomes important for the university to emphasize this aspect of investigations. Still less legitimate is it for a worthy university to exploit the contributions to knowledge which it has been fortunate to have developed within itself as an advertisement of its merits, not in this respect mainly but in general. There is no feature in the management of American universities that in my mind so easily arouses disgust and despair as this much varied but always objectionable heralding of their opportunities and successes. This field may properly be left to the manufacturers of proprietary and dietary specialties.

Investigation for discovery is a university function because of its incentive to the highest activity of those who in their several departments approach the confines of acquired knowledge and attempt to extend or to modify them; because of its contribution to the totality of the university spirit which permeates and stimulates every output of its energies; and, independently of these, because the advancement of learning by the creative capacities of the men of greatest endowment is in itself as proper a function of a university as teaching or the maintenance of libraries and museums.

Regarding its relation to the individual development of the professor, it would be foolish to ignore the fact that teaching and research do not always make an harmonious pair. There will always be in letters and in science a group of men, often marked by genius as her own, who are keenly sensitive to the restraints and routine of instruction. Lowell said that being a professor was not good for him; it damped the gunpowder of his mind, so that "when it took fire at all (which wasn't often), [it] drawled off in an unwilling fuse instead of leaping to meet the first spark." The joy of feeling that the marks of the ball and chain had worn off induced him to write, "If I were a profane man, I should say, 'Darn the College!'" Some mutterings of similar import may occasionally be overheard in the vicinity of laboratories and lecture rooms. The best teacher is not always an investigator, nor the best investigator a teacher. The university should be broad enough to provide for men of both types and set each to work at that which he does best. And yet, because of its influence upon the totality of the university spirit, I believe that in the long run the fruits of instruction will be choicest when they have been ripened in the sunshine of investigation.

To what extent universities will be willing to encourage investigation as a complementary obligation to their other functions is largely a practical question; it depends upon means of support, it depends upon a public spirit liberal enough to appreciate and provide for its development in a spirit of the husbandman who plants the tree the fruits of which he shall not live to enjoy. 'Serit arbores quae seclo prosint alteri.' There are welcome signs that such a spirit is not foreign to our civilization, and that this is one of the respects in which the twentieth century may be expected to exceed the achievements of the nineteenth.

So far as I have attempted to crystallize my contribution to this symposium it may be said to center about these points: Investigation constitutes a motor or expressive factor in education at a stage in which that factor becomes particularly significant. It occupies an important place in the university by reason of its disciplinary value in the direction of self-reliant activity. The place of investigation in building up the spirit that makes for the safest and sanest progress is no less conspicuous. Investigation for discovery is a function coordinate in worth with other purposes of a university, and is more likely than almost anything else to keep the mind of the professor from 'drawling off in an unwilling fuse,' and to make it ready to leap to meet the first spark.

JOSEPH JASTROW.

UNIVERSITY OF WISCONSIN.

IT may be conceded in the beginning of this discussion that a modern university is an institution which devotes attention to all subjects information upon which can be systematized or reduced to a science, and that it is constantly striving to extend the boundaries of knowledge in every branch of human inquiry.

In its strictly educational function it develops a proper conception of these subjects in the minds of its students by the logical and inspired presentation of certain basal facts and underlying principles, with which the learner may build up the mental edifice representing the structural aspect of each subject in its completeness or incompleteness.

With a fairly general agreement upon these points it might be said that the subject for discussion is one which vitally concerns the integrity of the university, and any question of the abstract relation of the university to investigation would imply a most serious state of affairs. I take it for granted, however, that the real theme for consideration is not the ethical relation of the university to research, since its obligations in the matter are invariable and undeniable, but rather one of the practicability and pedagogical expediency of carrying out this obligation.

Can the facilities of a university be used to advantage in the furtherance of research, and what influence does effort of this character exert upon its pedagogical functions?

The most prominent feature in the majority of our universities under their present organization is undoubtedly their academic department, in which the older, often miscalled the elementary, parts of the subjects are presented in a manner which absorbs the greater proportion of the facilities of the institution. The intent of such instruction is most commendable in its thoroughness and honesty of purpose, but here the good and honest intention, as with many others blindly followed, leads to a most iniquitous ending. No university of standing fills its chairs with men who are not prominent by the results of their investigations and active in their present prosecution. Having proceeded so far wisely and well, the administration then falters in its high purpose, and permits, rather insists that practically all of the energy of its members should be expended in the more or less mechanical duties attendant upon elementary instruction, especially in natural sciences, and fails entirely to provide either opportunity or facilities for the development of research work and its use in the presentation of the subjects. Such failure may be due to financial disability, though administrative lapses of judgment are not unknown or infrequent. In either case it is unfair and unfortunate to such a degree as to stretch the conception of honesty to its utmost limits, and to make the name of the university a travesty. Such non-appreciation of the actual importance of investigation is most conducive to stagnation, or indeed it may be taken as a symptom of it, and its deadening, thwarting effect is doing more to retard the development of the American university than any other one cause.

The presentation of any subject by an instructor who is not participating in its development will lack freshness of treatment, sharp distinctions between established and speculative deductions, will be more or less dogmatic, and will fall far short of its possible value, both for culture work and professional training. To this sweeping statement I am bound to add that there are a few teachers, not investigators, whose apparent success in instruction is due to an enduring and contagious enthusiasm which implants a permanent interest in a subject, in the mind of a student, which may lead him to follow it later and elsewhere to a more orderly and natural attack, from which he will gain a proper perspective for the first time. The arousing of enthusiasm and the imparting of information do not constitute the highest form of instruction however, and the teacher who does no more, fails not only in his special office, but also in his duty to bear a share in carrying out the obligations of the institution to society.

So far as investigation as a method of teaching is concerned, it is to be said that the acquisition and systematization of information gained in this manner, have a value both for culture and professional training lacking in any other method. It is a procedure by which the student is led to grasp the chief concepts included in a subject, the principles to be deduced from their orderly arrangement, to trace the manner in which every increment of new fact or advanced thought has been accumulated, and to follow the technique of this development in making his own acquaintance with the subject in its known aspects. So far he has been an investigator merely as a matter of discipline. Later he may project his activities beyond the boundaries of the subject, and by contributions of his own winning, alter its limits and make a readjustment of its generalizations possible and necessary. The value of this investigating, or find out for himself, method of learning is too well established to need more than mention at this time; a value clearly conceded by its almost universal usage. Whether or not a student should be led into the specialization necessary to make discoveries, in his undergraduate days, is a question which may be answered only in the light of information as to his training, his purposes, and his mental capacity. The same may be said of the graduate student, except that the value of investigation for discovery is more immediate in his case if his graduate work logically follows his earlier training.

With the realization of the value of research in the university, it may be said that no worker who is thoroughly in earnest will fail to find means of attack upon some of the problems pressing in upon him, and to use this method in the presentation of his subject, no matter under what straitened circumstances he may find himself. The investigator who does not show this adaptability will certainly encounter ample opportunities for unhappiness.

With a devotion to research in its faculties it needs but the expressed appreciation of the administration to promote the pedagogical practice of investigation to a creditable degree, even if the material facilities are lacking. The extension of investigation to a point where it may actually contribute to the development of a branch of knowledge will depend very largely upon the actual financial resources of the institution, although the born investigator is not easily turned from his path. In any case the needs of a university for research facilities are quite as elemental and quite as pressing as for libraries, chapels, memorial halls, gymnasiums, or any other part of the institution's mechanism, and should receive corresponding attention from those in charge of its organization and administration.

The following statements may be made in conclusion:

1. One of the primal duties of the university is the furtherance of research.

2. The presentation of subjects by instructors not engaged in research will lack originality of treatment and will not be properly inductive.

3. Investigation is itself a method of advanced teaching by which a student comes to a full realization of the structural aspect and relations of a subject, participates in its development, strengthens his mental grasp and broadens his powers of generalization; a method by which the highest form of culture and training is secured.

4. Investigation is, therefore, not only an obligation of the university to society and to its students, but also one of its most effective weapons.

5. Any tendency to the restriction or curtailment of the opportunities for research is to be regarded as a most alarming retrograde movement, which may in time vastly impair the usefulness of the institution compelled to take this step, and is certainly indicative of disabled function or evasion of one of the plainest duties of the university.

D. T. MacDougal.
N. Y. Botanical Gardens.

It is hardly necessary to emphasize here the importance of investigation as a part of the training of the university student.

Training in research methods is chiefly valuable in that it stimulates the perception and the imagination and increases the power of self-guidance and immediate productivity. As a means of instruction it is slow and cumbersome and often fails to accomplish its object.

With the rapid growth, in recent years,

of the spirit of research, instruction in the methods of research is regarded as an essential part of the teachers' university training. The same kind of instruction is being rapidly transplanted into the college curriculum, where it may form part of the work of advanced students during their junior and senior years.

We shall not try to point out here the value of research to the university, or to discuss what may be done to give it new scope and direction. Let us rather inquire whether there is not a tendency to confound the university attitude toward investigation as a method of training, with that of the learned society or academy toward research as an end, and whether, as a result of this confusion, our higher educational institutions are not substituting too extensively a training in investigation for more direct methods of instruction.

The criticism may be fairly made that in research work an enormous amount of time is devoted to mechanical details that do not yield adequate returns, either in instruction or in training; that much of this work is begun before the student is properly prepared to undertake it, and done at the expense of the best opportunity he is likely to have of acquiring a broad, sympathetic culture, and a secure foundation knowledge of the subject in which he proposes to specialize; and finally, that the research work to which the student devotes so much of his time rarely, if ever, serves as a preparation for the kind of work by which he expects to earn a living,—namely, teaching in the college or secondary schools.

It seems to me that such criticisms are largely justified, and that they are specially applicable to the biological student, whom I shall have in mind in the discussion that follows.

This is mainly due to the nature of biological work, and to the character of the biologist. The latter is generally an enthusiast who follows his subject for its own sake, without hope of the large financial rewards of the inventive chemist or physicist. In rare cases he may be a man of wealth and leisure, but more generally he has very moderate means and is without the best preliminary training. In the great majority of cases, he must earn his living by teaching, and use his leisure time only for research.

In biology the frontier separating the known from the unknown is everywhere close at hand, and new methods of research make it easy for comparatively untrained workers, with a little guidance, to bring important facts to light.

It is not necessary to devote the long years of training required in music and art, to make the eye and hand of the biologist effective instruments for the performance of his work, and the apprehension of the mere materials with which he deals, taken alone, does not make great demands on his mental resources.

The daily occupation of the biologist may be so absorbing, that once he begins to section and stain, and put things safely away in bottles, he is likely to keep on doing so till he dies.

There is, therefore, a great temptation for the biological student to begin his creative work at an early period, and he is eager to do so because it gratifies his pride to be investigating something, and because, on the whole, investigation is a very entertaining occupation. The instructor is not likely to oppose his inclinations in this direction, since he finds it an easy way of keeping the student busy, and incidentally of clearing up little problems he has no time to work out for himself.

But there is probably no other subject in which there is greater danger of too early specialization than biology, because there is no other science which sends its roots more deeply or intricately into other sciences, or in which the personal equation, the character and training of the man, exerts a greater influence over the interpretation of results.

As the biologist's greatest skill is shown in the marshaling and weighing of a multitude of what must always remain incomplete and fragmentary data, his best preparation for such work will be the formation of that sound judgment which comes from a wide knowledge of his special subjects, and something more than the mere vocabulary of related ones.

The college courses do not usually give the required training, not for lack of time, but because so much time is wasted in getting ready to teach, and in observing the mouthings of science, that there is none left to hear what she has to say.

In some instances the instructor apparently tries to find out how long he can instruct without telling anything, and how long he can keep the student guessing what he is expected to see. After the student has made careful drawings of various organs and covered them with unintelligible names, he is often left to draw his own conclusions as to their meaning and function. This method may satisfy the student's curiosity to get a good interior view of the organization of an earthworm, but it does not enable him to discover what the science of biology has to say on the subject. It is as though one should begin a course in the science of football by requiring the student to make careful drawings of the stitching on the ball, and to section its germ layers, and then leave him to form his own notions as to how the game is played. Such a method is said to be of value in cultivating the powers of observation. But if the teacher of biology would teach biology only, and let the powers of observation alone, better results would be obtained. In my own judgment, you can hardly tell a student too much, or tell it too quickly, provided you tell it so that he can understand.

In the university the student often suffers from a similar lack of direct instruction. He generally finds that two kinds of courses are open to him: in one the treatment of the subject is so elementary that he can afford to ignore it; in the other some subdivision of it is discussed in great detail, and perhaps necessitates the expenditure of so much time and energy in the use of investigation methods that he does not want it, or cannot afford the time to take it.

In these courses, the instructor prides himself on giving the very latest report of the hour, with much controversial matter, better suited for the archives of some learned society than to be detailed in the class or lecture room. A prolonged diet of this kind is depressing, and is apt to leave in the mind of the student a succession of vague impressions of small educational value, and a feeling that it is more important that a certain investigator should receive full credit for having made a discovery than it is to give that discovery its due weight and position.

It has been said that biological instruction in America is not what it pretends to be, because the botanical side of the subject is neglected and most of the time given to zoology. But even the zoological instruction, that is supposed to be biological, is itself one-sided, since it may be treated from the purely morphological standpoint, ignoring altogether the experimental, physiological and ecological sides of the subject.

With all this special work goes a great deal of technique, something that readily degenerates into an interminable puttering over different methods, with very little attention given to the real questions to be solved by them.

On reaching the university the student's first thought is to obtain some problem for his doctor's thesis, and, if he is fortunate, in the selection or assignment of a workable subject, and can obtain material to work with, his best energies are henceforth centered round that particular work, for he is led to believe that his future career depends largely on his discovering at once something of importance.

He feels that his time has been thrown away if at the end of a certain period he has no results on hand worth publishing. In the absence of such results and in his haste to get his degree, there is danger that after prolonged meditation he may unconsciously supply the deficiency by giving to his discoveries an importance they do not possess. By padding his paper with personal and irrelevant details, or by picking an unnecessary quarrel with his predecessors, and with the aid of an elaborate historical summary, he can generally get together an article of sufficient dimensions to produce a favorable impression on the biological community, excepting, of course, the half dozen or so individuals that read it.

In his research work the student is sustained by the thought that he is carrying on some profound investigation. But his work is largely mechanical. It may require a great deal of patience, a little manual skill, and perhaps some intelligence, but it very rarely shows any genuine originality. The student is really seeing and doing what he is told for he has not sufficient knowledge of his subject to steer his own course, or to clearly grasp the significance of the question at issue. Much of the research work of the faithful student type is of this nature. In fact, the instructor does the research, and the student the manual labor.

Another evil likely to arise from the over-emphasis of research work is the danger of a great waste of time and energy on sterile problems. If it is downright cruelty, as Huxley says, to add one unnecessary hour to the work of the medical student, it is no less an offense to assign a line of special inquiry to a candidate for the doctor's degree with a possibility that at the end of one or two years his chances of getting the degree are as far off as ever, because through no fault of his own the work gave negative results, or because his results have been anticipated elsewhere. Another student, more fortunate in the assignment of his problem, may get his degree with the expenditure of half the time and labor.

Of course it may be urged that in most cases no one can know whether a given problem will be fruitful or not till it has been tried, and the candidate must take his chances. He must, no doubt, take his chances in after life, and he accepts the conditions more or less cheerfully, provided he is not asked to wager more time and strength on the hazard than are honestly his.

Meantime the candidate for a doctor's degree has been so absorbed in his research work, that he has not had time to think about his own development or his examinations. It is usually assumed that, when the time comes, 'a few weeks hard plugging will fix that all right,' and experience generally justifies the assumption. In a case that came directly under my own observation, a Japanese student of zoology was to demonstrate his knowledge of botany by describing how they cultivated tea in Japan.

After two or three years of investigation, the graduate student is liberated with an exaggerated idea of his own importance as a contributor to the world's store of knowledge, and quite untrained in the only work he is likely to do well, or even have a chance to try, namely, teaching in the secondary schools.

The layman, looking for a teacher with an up to date equipment for his work, may be impressed by the doctor's voluminous treatise, but he will probably discover, when it is too late, that his candidate has but one imposing garment to conceal his unfitness for the work required, or, worse still, may find that he does not want to teach at all, but to investigate.

It may take several years for such a misfit teacher to adjust himself to his proper environment, and to discover that it is worth more to be a good neighbor and a useful man in the community than it is to be known in Germany.

In conclusion, therefore, it seems to me that by the over-emphasis of research the university is in danger of sacrificing the sound, symmetrical education of the individual for the sake of a too rapid growth of science. The university student should be trained in the methods of investigation, because it may give him fertility and power, not because it is his business or duty to contribute something new to the world's store of knowledge.

As the value of his contribution may or may not afford a measure of his originality or of his ability to teach, the university should not insist too rigidly on an original contribution as a requirement for the doctor's degree, and should eliminate every possible element of chance that may deprive the candidate of his well-earned license to teach, or that may unnecessarily prolong his term of apprenticeship.

The examination for the doctor's degree should precede rather than follow the approval of a thesis, in order to check too early specialization and an undue haste in the publication of fragmentary research work.

The biological material already available for teaching should be condensed and put into logical order for purposes of more direct instruction, and the educational requirements of the medical man, the teacher, and the professional investigator should, so far as necessary, be met separately.

The physiological and experimental sides of biology should receive greater attention, and that kind of out-door work on living animals in their natural surroundings, for which the marine and lake laboratories offer such excellent opportunities, should be specially developed, because among other reasons, of its bearing on the nature work in the public schools. The work done in these laboratories should be formally recognized as part of the requirements for the higher degrees, and the laboratories themselves grafted on to the university and college so as to form as much a part of their equipment as do the library and museum. Results of the greatest importance for biology, in all its relations to education, will surely follow coöperation in this direction.

DARTMOUTH COLLEGE.

AMERICAN MATHEMATICAL SOCIETY.

THE sixth annual meeting of the American Mathematical Society was held at Columbia University on Thursday, December 28, 1899. On the same and the following day the Chicago Section met at the University of Chicago. Occurring in the holidays, these two meetings are more easily attended than those of other seasons, and afford better opportunities for personal conference and discussion. The annual meeting offers the additional interest of the election of officers, the presentation of annual reports which regularly bear testimony to the remarkable prosperity of the Society, and the general marking of the close of one year of progress and the opening of another. An especially attractive feature of this year's annual meeting was the scholarly Presidential Address of President R. S. Woodward on 'The Century's Progress in Applied Mathematics.' This address, which appears in the present number of SCIENCE, as well as in the next number of the *Bulletin* of the Society, was delivered before an appreciative audience of nearly eighty persons, the members of the American Physical Society attending, by invitation, in a body. During the reading of the address and of Professor Pupin's paper, the chair was occupied by President H. A. Rowland, of the Physical Society. As predicted in the report of the October meeting, the relations of these two societies are becoming more and more intimate and cordial, a tendency which cannot be too highly commended. The results are mutually beneficial. The attendance of members of the Mathematical Society increased more than seventy per cent. over last year, this Society furnishing nearly one-half of the total attendance at the meeting of both bodies.

At the annual election the following officers and members of the Council were chosen: President, R. S. Woodward; First Vice-President, E. H. Moore; Second Vice-President, T. S. Fiske; Secretary, F. N. Cole; Treasurer, W. S. Dennett; Librarian, Pomeroy Laden; Committee of Publication, F. N. Cole, Alexander Ziwet, F. Morley; Members of the Council to serve for three years, Simon Newcomb, Oscar Bolza, L. A. Wait. Suitable resolutions were adopted on the retirement of Professor Jacoby from the office of Treasurer after a service dating from the founding of the Society.

The Council announced the election of the following persons to membership in the Society: Professor William Beebe, Yale University; Dr. J. V. Collins, State Normal School, Stevens Point, Wis.; Professor A. R. Forsyth, Trinity College, Cambridge, England; Professor M. W. Haskell, University of California; Mr. C. A. Noble, University of California; Miss E. N. Martin, Ph.D., Ardmore, Pa.; Mr. E. B. Wilson, Yale University; Miss R. G. Wood, New Haven, Conn. Four applications for membership were reported. The total membership of the Society is now 342, a gain of 27 during the year. About 110 papers were presented before the Society during the year as against 83 in 1898.

The first number of the *Transactions* is now in press and will appear in January. Later numbers will appear at intervals of three months.

The following papers were presented at the Annual Meeting:

(1) DR. G. A. MILLER: 'On the groups which have the same groups of isomorphisms.'

(2) PROFESSOR MAXIME BÔCHER: 'On regular singular points of linear differential equations of the second order whose coefficients are not necessarily analytic.'

(3) DR. VIRGIL SNYDER: 'On cyclical quartic surfaces in space of n dimensions.'

(4) DR. VIRGIL SNYDER: 'On the geometry of the circle.'

(5) MR. W. B. FITE: 'A proof that the commutator subgroup of a group may contain operators which are not commutators.'

(6) J. E. CAMPBELL, M.A.: 'On the types of linear partial differential equations of the second order (in three independent variables) which are unaltered by the transformations of a continuous group.'

(7) PROFESSOR L. E. DICKSON: 'Proof of the existence of the Galois field of order p^r for every integer r and prime number p.'

(8) DR. E. M. BLAKE: 'On plane movements whose point loci are of order not greater than four.'

(9) PROFESSOR R. S. WOODWARD: Presidential Address: 'The century's progress in applied mathematics.'

(10) PROFESSOR M. I. PUPIN: 'The propagation of electrical waves over non-uniform conductors.'

(11) PROFESSOR HENRY TABER: 'The singular transformation of a group generated by infinitesimal transformations.'

(12) DR. J. I. HUTCHINSON: 'On certain relations among the theta constants.'

(13) PROFESSOR E. O. LOVETT: 'Singular solutions of Monge equations.'

F. N. COLE,
Secretary.

COLUMBIA UNIVERSITY.

SCIENTIFIC BOOKS.

Everyday Butterflies. A Group of Biographies. By SAMUEL HUBBARD SCUDDER. Boston and New York, Houghton, Mifflin & Company. 1899. 12mo. Pp. viii + 386. 9 plates, 23 figures; 48 figures in text. Price, $2.00.

This tasteful little volume contains an account of the life-history, habits, and distribution of sixty-two species of the commoner butterflies, which are found in the Eastern States and the Canadian provinces of Quebec and Ontario. It is illustrated by nine plates, eight of which are done in colors, the other being a carefully executed and faithful representation in black and white of an enlargement of the interesting chrysalis of *Feniseca tarquinius*, the curious aphidivorous habits of the larva of which are fully explained by the author. The illustrations in the text are numerous and excellent, and, with the plates, will enable the reader to easily identify the species when encountered in nature.

The study of butterflies is every year gathering new devotees, especially from the rapidly-growing leisure class, and the ranks of the young in our schools and colleges. No field of observation is more accessible and interesting, and none more likely to yield valuable results, from the standpoint of the biologist, than that of entomology. Books, like the one before us, which combine scientific accuracy with a grateful flavor of the woods and the fields, can not fail to stimulate those who are their happy possessors to make researches, which will give charm and delight to life, and may prove of positive scientific interest.

Everything which falls from the pen of Dr. Scudder possesses the merit of literary grace, and, with but very few exceptions, absolute scientific accuracy. If any adverse criticism in general could be passed upon the writings of our learned friend, it is that in his zeal for precision of description and thoroughness of treatment he at times becomes a little prolix. This, however, is a trait wholly absent from the pages of the present book, which are sprightly and popular in style, while profoundly instructive.

Issue must be taken with two statements made by the author on page 281. In speaking of the chrysalis of *Feniseca tarquinius* he says: "Curiously enough, a similar ape's face is seen in the chrysalis of an African butterfly of another genus not very closely related to *Feniseca*, and in an Indian species of the same Oriental genus. Now, in these two cases there is a strong probability that their larval food is plant lice." The reference is to the chrysalis of *Spalgis s-signata*, Holland = *S. lemolea*, H. H. Druce, which I had the pleasure of describing and figuring in *Psyche* Vol. VI., p. 201, Plate IV., and to the chrysalis of *Spalgis epius*, Westwood, described and figured by Aitken in the eighth volume of the *Journal* of the Bombay Natural History Society, Plate A. A careful examination of the structural peculiarities and of the preliminary stages of the genus *Spalgis* shows that it is very closely related to our North American genus *Feniseca*, and any general classification of the lepidoptera belonging to the family Lycænidæ which did not place these genera in propinquity would be in error. The statement of the author that in the case of the two species of *Spalgis* mentioned "there is a strong probability that their larval food is plant lice," overlooks the fact that in both cases the aphidivorous habits of the larvæ have been positively ascertained.

Points like these relating to the habits of exotic species, which are only alluded to in passing, do not in the slightest degree affect the value of the book for the circle of readers for which it is particularly intended, and it may be recommended as altogether one of the most pleasing and instructive contributions made in recent months to a branch of science which is daily growing in importance and popularity.

W. J. HOLLAND.

CARNEGIE MUSEUM, PITTSBURG.

Practical Exercises in Elementary Meteorology. Ginn & Co., Boston. 1899. Pp. xiii + 199.

One does not expect a laboratory manual to be interesting, yet Mr. Ward's volume will prove attractive reading to any one interested in the teaching of meteorology. It contains materials for laboratory work for all school ages and includes the exercises that within a few years constituted the laboratory work in Mr. Ward's course at Harvard.

The author does himself injustice when he states the object of his book is "to lead the pupil to the independent discovery of the most important facts in our ordinary weather conditions." The very judicious comments that accompany the exercises tend rather to the rational end of illustrating the laws of meteorology and the method of meteorological study. The well-considered suggestions to teachers propose that in primary schools the attention of pupils be called on occasion to the more obvious relations of the various weather elements to one another and to us. This as a preparation for the exercises of this volume.

Parts I. and II. suggest observations, instrumental and uninstrumental, to be made by one and another member of the class from day to day and kept in a permanent record throughout grammar and high school years. Mr. Ward has prepared numerous questions designed to bring out the simpler relations of the various elements.

Part III.—Exercises in the construction of weather maps—is presumably to be used in high school years. A table of meteorological data for six consecutive days at all weather bureau stations throughout the country is printed at the end of chapter III. (not chapter VIII., as stands printed always in the text). From this pupils are to construct on blank weather maps the isotherms and isobars for each day and the corresponding temperature and pressure gradients. Other blank maps are to be filled out with wind arrows for each day, and still others with the signs for clear and cloudy sky, etc. Besides these construction exercises others are based on the comparative study of the maps thus drawn.

Part IV. contains Correlations of the Weather Elements and Weather Forecasting. These exercises follow naturally on the preceding, going to published weather maps for their data and tending to illustrate the cyclonic and anticyclonic groups of phenomena and their relationships.

These are very valuable exercises from the nature of the results sought and from the fact that they have that definite character which the young student demands. Generalities are his abhorrence, and while all his studies are in the direction of training to generalize from sufficient data he must be allowed a firm footing on particulars at the outset. The demand that he *formulate a general rule* (p. 117) is one that would leave many a high school pupil bewildered. Perhaps he could do it if told in other words.

Some of the problems in Part V. will be beyond the range of many pupils for this reason of their general character. Moreover, as they seek valid results on questions of importance, such as the relation of relative humidity to the direction of the wind, some use should be made of more extended collections of data, made more carefully than is practicable for school classes. It is a pity to base inductions on any but the best of data. I presume all who are teaching young people to make observations are agreed that the immediate object is to train their faculties and show them the scientific method rather than to acquire results. Indeed, it seems to me important that pupils should be led to recognize clearly the rude character of their work as compared with good standards. For this reason it is especially desirable to avoid drudging at observational and mechanical work. Only so much observation is desirable as will help the pupil to understand the process. When it comes to induction he should use the best results specialists have been able to produce. For similar reasons in some of the weather map exercises in Part III. use might be made of the government maps rather than of those produced by the pupil himself, as some of these will be too bad to use and most of them less easily read than the printed maps. I find classes of 13 and 14 years require three fifty-minute periods for the first satisfactory production of one day's isotherms. To reproduce six such days and then six more for isobars and yet more for other elements is to impose task-work. Most teachers will be content with fewer such tasks and as soon as the principle is grasped pass on to use the printed maps.

Mr. Ward has not claimed, however, to give us exercises in shape for immediate use, but rather to offer material from which we could select according to our needs. The materials he offers are abundant and available.

The descriptions of instruments are very clear and simple, and the historic notes and the comments on phenomena and relations between man and the weather very interesting.

Among the instruments one is rather surprised to see the nephoscope, nor is maker or price indicated in the list of instruments. It is a pity to put a doubly-folded sheet like that in Chapter III. in a school-book. It will certainly be torn in the first year. By printing on both sides one fold might have been avoided and there is no good reason why all the data might not have been printed in the text as wanted day by day.

The fact that so many problems are worked out in the book makes it easier reading but will require the books to be closely watched in the class-room.

The Weather Bureau Meteorological Tables are inserted at the end of the book with an excellent appendix on the 'Equipment of a Meteorological Laboratory.'

The book should prove valuable to every teacher of meteorology.

M. S. W. JEFFERSON.

ELMWOOD, MASS., December 19, 1899.

Bacteria, especially as they are related to the Economy of Nature, to Industrial Processes and to the Public Health. By GEORGE NEWMAN, M.D., Demonstrator of Bacteriology, King's College, London. The Science Series. New York, G. P. Putnam's Sons; London, John Murray. 1899. Pp. 348.

The fact that bacteria are concerned in a variety of natural processes and do not devote themselves exclusively to the causation of disease is beginning to touch the popular imagination and to create a demand for treatises that shall deal with the subject of bacteriology from a general biological standpoint rather than a strictly medical one. An attempt to meet this need has been made in the present instance. Dr. Newman discusses, under separate chapter-heads: The Biology of Bacteria, Bacteria in Water, Bacteria in the Air, Bacteria and Fermentation, Bacteria in the Soil, and Bacteria in Milk, Milk Products and other Foods. These six chapters cover 239 pages out of 348. A chapter is then given to The Question of Immunity and Antitoxins, which is followed, by what seems a singular inversion, with one on Bacteria and Disease, and the book ends with a chapter on Disinfection. Many topics of great interest are considered in these pages, and the author's selection of material and mode of treatment will command general approval. The book is marred, however, by a lax and involved style and contains so many errors of statement as to call seriously for revision. On page 30, for example, it is stated that "boiling for thirty to sixty minutes will kill all bacilli and all spores," and on page 79, "moist heat at the boiling point maintained for five minutes will kill all bacteria and their spores." These statements are not in accord and neither is correct. On page 16 it is erroneously stated that "*Micrococcus agilis* is the only coccus which has flagella and active motion." In the description of Van Ermengem's method of staining flagella (p. 63) it is probably through a typographical slip that a 25.5 per cent. solution of silver nitrate is recommended, and surely the use of boric acid in place of osmic acid in the fixing bath is an unusual procedure. It is hardly a careful form of statement to refer to the power of the tetanus bacillus to produce disease as its 'regular function' (p. 32). The author's definition of the antitoxin unit (p. 263) is incorrect. It is not necessary to multiply instances, but it is to be hoped that subsequent editions may find some of these blemishes removed, since they unquestionably impair the value of an otherwise interesting and useful book.

Two examples of the author's somewhat enigmatic style may be given: "Yet, whilst this general fact is true, we must emphasize at the outset the possibility and practicability of securing absolutely pure sterile milk. Recently some milking was carried out under strict antiseptic precautions, with the above sterile result" (p. 181). "*Budding* occurs in some kinds of yeast, and would be classified by some authorities under spore formation, but in practice it is so obviously a 'budding' that it may be so classified" (p. 16).

E. O. J.

A Treatise on Crystallography. By W. J. LEWIS, M.A., Professor of Mineralogy in the University of Cambridge. Cambridge Natural Science Manuals, Geological Series. Cambridge: At the University Press. 1899. 4to. Pp. xii + 612.

This new text-book of crystallography presents the modern views as to the classification of crystals based on the principles of symmetry. It is devoted exclusively to the geometrical relations of crystal forms and to methods of determining these relations and of representing them graphically.

In the first nine chapters the general properties of crystals are described, including very full discussions of symmetry relations and of the properties of zones. The discussion is geometrical rather than analytical and follows more or less closely the treatises of Miller and Story-Maskelyne. In Chapters VI. and VII., treating of crystal drawing and methods of projection, no mention is made of the gnomonic projection, which now occupies an important place in crystallographic discussion.

The treatment of the general optical and physical properties of crystals of the different systems contained in Chapter X. is very brief and seems hardly adequate in a work of this character.

Chapters XI. to XVIII. are devoted to descriptions of the thirty-two classes of crystals. The classification of these types is essentially that of Groth. A feature of this part of the work is the presentation of a great many examples of crystals of various substances in each class, each crystal being worked out in detail with all the logarithmic computations necessary for the determination of its elements and the indices of its forms. Directions for drawing the forms are also not infrequently given after their determination, and a great deal of useful information in practical crystallography may be found scattered through these examples. But their number seems rather more than necessary, adds very much to the bulk of the book and so scatters the desired information as to reduce its usefulness.

In the final chapter on Goniometers but scant justice is done to the theodolite goniometer, no reference being made to the admirable graphic methods of discussing measurements made with it developed by Federow and Goldschmidt.

A complete index concludes the volume. The excellent typography and text figures deserve a word of praise.

The book hardly commends itself to beginners in crytallography, being too elaborate in its treatment and too mathematical in its presentation. Its greatest service will be to more advanced students doing practical work in the study of crystals.

C. PALACHE.

SCIENTIFIC JOURNALS AND ARTICLES.

THE contents of the *American Journal of Science* for January are as follows:

'Products of the Explosion of Acetylene,' by W. G. Mixture.

'Glaciation of Central Idaho,' by G. H. Stone.

'Pogonia Ophioglossoides,' by T. Holm.

'Graftonite, a new Mineral from Grafton, New Hampshire, and its Intergrowth with Triphylite,' by S. L. Penfield.

'Explorations of the *Albatross* in the Pacific Ocean,' by A. Agassiz.

'Analyses of Italian Volcanic Rocks, II.'; by H. S. Washington.

'Constitution of the Ammonium Magnesium Arseniate of Analysis,' by M. Austin.

THE *Astrophysical Journal* for December contains the following articles:

'Robert Wilhelm Bunsen,' by Henry Crew.

'The Wave-Length of the Corona Line,' by C. A. Young.

'Density of Close Double Stars,' by Alexander Roberts.

'The Densities of the Variable Stars of the Algol Type,' by Henry Norris Russell.

'Note on the Spectrum of *P. Cygni*,' by A. Bélopolsky.

'Apparatus and Method for the Photographic Measurement of the Brightness of Surfaces,' by J. Hartmann.

'The Great Sun-Spot of September, 1898,' by J. Fényi.

'A Spectroscope of Fixed Deviation,' by Ph. Pellin and André Broca.

'Researches on the Arc-Spectra of the Metals,' by B. Hasselberg.

THE contents of *Appleton's Popular Science Monthly* for January include 'The Advance of Astronomy in the Nineteenth Century,' by Sir Robert Ball, 'The Applications of Explosives,' by Professor C. E. Munroe, 'Scenes on the Planets,' by Mr. Garrett P. Serviss, Professor Ward on 'Naturalism and Agnosticism,' by Mr. Herbert Spencer, and 'Old Rattler and the King Snake,' by President David Starr Jordan. The *Monthly* is somewhat altered in appearance, and the price is $3.00 per annum. We trust that its influence may be correspondingly increased.

St. Nicholas magazine, which is so popular with young people and has on the whole exercised such an excellent influence, will with the new year add a department of natural history, under the editorship of Mr. Edward F. Bigelow, editor of *Popular Science*. Six pages, monthly, will be devoted to this new department. Two of these will be given up to the out-door world; two more to indoor study and research, both in nature and science; one to correspondence from the children; and one to a department of 'Questions and Answers.'

SOCIETIES AND ACADEMIES.

PHILOSOPHICAL SOCIETY OF WASHINGTON.

The annual meeting of the Society was held at the Cosmos Club on December 23, 1899. The usual reports of the Secretaries and Treasurer were read and an Amendment to the Constitution proposed at the last annual meeting was adopted. By this action membership in the General Committee is subject to new conditions as far as the ex-Presidents of the Society are concerned.

The election of officers for the coming year resulted as follows:

President: G. M. Sternberg, Surgeon General U. S. A.; *Vice-Presidents:* H. S. Pritchett, Superintendent Coast and Geodetic Survey; C. D. Walcott, Director Geological Survey; L. F. Ward, Geological Survey; Richard Rathbun, Smithsonian Institution; *Secretaries:* J. E. Watkins, National Museum; E. D. Preston, Coast and Geodetic Survey; *General Committee:* Cyrus Adler, Library of Congress; W. A. DeCaindry, War Department; J. H. Gore, Columbia University; G. W. Littlehales, Navy Department; H. M. Paul, Naval Observatory; F. W. True, National Museum; C. K. Wead, Patent Office; I. Winston, Coast and Geodetic Survey; C. F. Marvin, Weather Bureau.

E. D. Preston,
Secretary.

SCIENCE CLUB OF THE UNIVERSITY OF WISCONSIN.

The December meeting of the Science Club of the University of Wisconsin was held on the evening of December 18th, the program of the evening being a paper by Mr. S. M. Babcock, dealing with the fat globules of milk.

Mr. Babcock stated that, although the fat globules of milk were discovered about two hundred years ago, no accurate knowledge of their structure, number or size was gained until quite recently. Two hypotheses have been advanced regarding their structure. One is that they are surrounded by a thin membrane of albuminous matter which prevents their uniting when they come into contact and protects them from the solvent action of ether when this is shaken with milk, unless a little acid or alkali is first added to dissolve the membrane. The other hypothesis holds that the globules are free particles of fat emulsified with the serum. It was shown that all phenomena which have been considered to favor a membrane are such as occur also in artificial emulsions, where no true membrane can exist if the fat globules are as small as those of milk, and it was, therefore, concluded that milk is an emulsion. The method of counting fat globules by means of capillary tubes was described and the circumstances which affect their number and size were discussed with the aid of lantern slides.

Wm. H. Hobbs.

THE ACADEMY OF SCIENCE OF ST. LOUIS.

At the meeting of the Academy of Science of St. Louis of December 18, 1899, Dr. Amand Ravold addressed the Academy on the necessity and means of filtering and otherwise purifying water, especially with reference to freeing it from bacteria, for municipal purposes. The speaker explained the sand-bed filter system as used in Germany and England, and the American mechanical system, represented by two commercial devices. The Wormser filter plate was also described and its characteristics were considered.

William Trelease,
Recording Secretary.

DISCUSSION AND CORRESPONDENCE.

OBSERVATIONS WITH THE MERIDIAN CIRCLE.

To the Editor of Science: In reading Professor Keeler's most interesting report upon the results of the Lick Observatory, as printed in Science for November 10, 1899, I find a statement on page 669 which, if not a misprint, eclipses all work of a similar character.

In connection with that portion touching upon the Meridian Circle, Professor Keeler states that during the year ending last September, and upon 106 nights, 6000 observations were made with the Meridian Circle.

Now the question I would submit, and upon which I would request information, does Professor Keeler wish it understood that 6000 star places were observed in that time, or are these numbers of observations made up of the determination of the right ascension, declination, nadir point, collimation, level and azimuth, each individual determination of these quantities to be counted as one observation ?

The above figures give as a nightly average 57 observations, and from my experience four or five observations per hour—I mean a complete determination in both right ascension and declination, when one is not working with an assistant and not in zone work—is about the limit.

When it is taken into consideration that one observer sets his circle, reads four microscopes, observes nine or eleven transits, makes two or more bisections in zenith distance, and records all these, reads his level at least once every hour, observes his collimation twice in an evening's work, an average of 57 observations per night is almost, if not quite, unrivaled.

But, as I said before, perhaps what Professor Keeler wished to convey by the word 'observations' is not what I have construed it, a complete determination of the two coördinates of the star place, but may contain two, three or four quantities, which he calls observations.

GEO. A. HILL.

NAVAL OBSERVATORY, WASHINGTON, D. C.

NOTE ON THE FOREGOING LETTER BY PROFESSOR HILL.

IN the part of my report to which Professor Hill refers in his letter, one observation means one complete determination of both coördinates of a star. A complete observation of the nadir (zenith) point and level is also, in accordance with the usual custom, counted as one observation. Collimation and flexure determinations and *mire* readings have not been included.

A reference to our records for the year covered by my report shows that the average number of stars, completely observed in both coördinates during this period by Professor Tucker, was fifty per night. With an assistant reading the microscopes the average number was sixty-two per night of from four to five working hours. The observations, as shown by their probable errors on complete reduction, are of the highest order of precision.

Doubtless this is quick work, but I believe that it is by no means of unprecedented rapidity. It is moreover obvious that a comparison of the work of different instruments, on the basis of such figures as those given by Professor Hill, may be quite misleading, since the rapidity with which observations can be made depends largely on the character of the work which is being done. With a full list like that of Mr. Tucker's during the past year, the stars culminate more rapidly than they can be observed, so that the list has to be gone over several times. The rate of observation then depends upon the observer's quickness and skill. With a list which contains many gaps, stars have to be waited for, and the rate depends upon the list alone.

JAMES E. KEELER.

DARK LIGHTNING.

TO THE EDITOR OF SCIENCE: My attention was drawn to Mr. Clayden's work by an article in *Nature* in which reference was made to a communication in one of the photographic journals. The note in the *Philosophical Magazine* I had somehow overlooked.

Mr. Clayden in his letter states that he was unable to obtain any results with the calcium light or with sunlight, and suggests that there may exist some difference between light from such a source and a source whose excitement is electrical, and that it is not safe to assume that the time factor is the only one, until the image of some non-electrical source has been reversed. I cannot see much difference between the calcium light and the arc, for in both we are dealing with an incandescent solid. To settle the matter definitely I have repeated the experiment with the revolving disc, using a calcium light, and obtained perfect reversed images of the slit on the first trial. Mr. Clayden's failure to get reversal with sources other than the spark was due, I imagine, to a too long exposure. The duration must be something less than 1/15000 sec. The exact point at which the reversing action begins can be easily determined by the revolving disc, and will be investigated shortly by one of our students.

R. W. Wood.

SCIENCE IN THE DAILY PRESS.

To the Editor of Science: In view of the appearance of several articles in the daily press relating to the case of the rapid calculator, Arthur Griffith, and purporting to be written by us, we beg to say that we have written no such article and have seen neither copy nor proof of any such article. We have given to reporters, when asked to do so, the principal facts reported before the Psychological Association. The published accounts have varying degrees of accuracy, a few of them being substantially correct. We are impelled to make this disavowal, for the reason that in some instances we are represented as making claims in regard to the case which we have never made. Persons interested are referred to the Proceedings of the Psychological Association and to the fuller statement of results presently to appear.

E. H. Lindley,
Wm. L. Bryan.

University of Indiana, Jan. 4, 1900.

'NEWSPAPER SCIENCE.'

To the Editor of Science: Some weeks ago in Science, and more recently in *The Psychological Review*, Professor J. H. Hyslop condemned in rather sweeping terms what he called 'newspaper science.' He was incited to do so by the publication of an erroneous and annoying report about himself. But while his irritation was certainly justified, his utterances were a trifle indiscriminate. And it is due both to the daily press, which he thus censures, and to the readers of your pages that attention be called to this fact.

It is true that certain papers indulge in untruthful and sensational stories about scientific men and scientific discoveries. But there are others that do not. To classify these two kinds of newspapers together betrays a lack of careful observation, or a wrong use of the logical faculty; perhaps both. Such a proceeding is hardly worthy of a man who pretends to a strictly scientific method in his ordinary work.

The fact is that, though they are only too scarce, one can easily find both newspapers and newspaper men who possess as keen a perception of the eternal beauty of truth, and are animated by as lively a sense of responsibility to the public, as the average professional scientist. A wider recognition of this fact is needed, not merely in the interests of justice, but in those of science also.

Now the number of persons who read technical reports and periodicals—astronomical, electrical, engineering, medical, psychological, and so on—is only about one-hundredth, or only a thousandth, as great as those who see only the daily papers. The vast majority of people could not understand this literature, anyhow. It needs interpretation and adaptation to popular comprehension. The daily paper, therefore, forms a highly important medium of communication between the original investigator and the general public; and, for better or for worse, it will always perform that function. If, then, men who are themselves engaged in scientific researches of value to mankind, or are identified with institutions devoted to the deposit of scientific collections, would abstain from aiding papers that are notoriously reckless, and encourage by word and definite favors those which treat scientific matters intelligently, conscientiously and accurately, they would promote the diffusion of knowledge to a far greater degree than is now possible, and check the very abuses of which Professor Hyslop complains. Not merely in their comments, but also in their active policy, professional scientists can do much to reform 'newspaper science' if they will.

Amateur.

New York, January 5, 1900.

BOTANICAL NOTES.

A NEW SOUTHERN FLORA.

Professor Tracy has prepared a little book under the title of 'Flora of the Southern United States' for use with Bergen's 'Elements of Botany' (Ginn & Company), which is intended to be used as an elementary manual for field work in systematic botany in the public schools.

The author recognizes the fact that "the ability to identify and name plants is not the object of botanical study, but it is a great assistance in attaining the knowledge which the true student of botany is seeking—an understanding of the laws of life in the vegetable kingdom." He has made it possible by means of keys and easy descriptions for the beginner to obtain some ideas as to how plants are classified, what botanists think as to the relationship of plant groups, and how to proceed in identifying an unknown plant. As far as it goes the book is a modern presentation of taxonomic botany. It deals with seed-plants only. Even the ferns so commonly included in manuals of this kind are not included, while the pupil gets no hint whatever of anything lower in the scale of plant life. This is a mistake, but a very common one, in botanical manuals, and we must perhaps overlook it for the present. It is pleasant to find a modern sequence of families (Engler and Prantl's) and a strictly modern nomenclature.

A NEW BOTANICAL JOURNAL.

WITH the December number the first volume of *Rhodora*, the new journal devoted to the botany of New England, was completed. The idea of a local botanical journal of high grade was a novelty, and its progress during the year was watched with much interest. Now at the end of its first volume we may look over what it has accomplished and judge as to whether a geographical limit is a wise one to be placed upon the field of a scientific journal. By far the greater number of articles deal with flowering plants, and are systematic rather than morphological, although the latter are by no means wanting. The ferns and mosses receive scanty notice, while the algæ and fungi are the subject of frequent papers and notes. Many of these papers have much more than local interest, and might with propriety have appeared in any botanical journal. Of course, there are some 'local notes,' some papers on 'noteworthy plants,' some on 'rare plants,' and some 'additions' to local floras. There is little if any of that species splitting which is too often the bane of local botany. The editorial announcement of a year ago stated that special attention would be given "to such plants as are newly recognized or imperfectly known within our limits, to the more precise determination of plant ranges, to brief revisions of groups in which specific and varietal limits require further definition, to corrections upon current manuals and local floras. to altitudinal distribution, plant associations and ecological problems." 'Ferns, mosses and thallophytes' were promised a share of attention. It is to the credit of the management that the program outlined at the outset has been so well carried out. *Rhodora* has shown that a geographically limited scientific journal may be successful and useful.

CHARLES E. BESSEY.
THE UNIVERSITY OF NEBRASKA.

THE CONFERRING OF UNIVERSITY DEGREES BY THE SMITHSONIAN INSTITUTION.

THE Chairman of the Senate Committee on the District of Columbia, Mr. McMillan, introduced, on January 2d, a bill entitled "An act to authorize the regents of the Smithsonian Institution to confer certain degrees and for other purposes." It provides:

"That the regents of the Smithsonian be, and they are hereby, authorized to appoint a board of five examiners, who shall, with the approval of the said regents, prepare and publish a schedule of courses of studies preparatory to the degrees of master of arts, master of science, doctor of philosophy and doctor of science. The said examiners shall from time to time hold examinations in the City of Washington for the said degrees; and, on the satisfactory completion by any candidate of the prescribed course of studies for either of the above mentioned degrees, shall recommend such a candidate to the regents of the Smithsonian Institution for such degrees. The said regents are hereby authorized to confer, under suitable regulations, the degrees above mentioned and also the honorary degree of doctor of laws. Provided, That no person shall be accepted as a candidate for the degree of master of arts or of doctor of philosophy who has not completed a course of study at least equivalent to the course of study required of candidates for corresponding degrees in the most advanced universities in the United States; and provided further, That the degree of doctor of laws shall be conferred on no more than five persons in any one calendar year.

"Sec. 2. The members of the board of examiners shall hold office during the pleasure of the regents of the Smithsonian Institution. Each examiner shall devote his entire time to the duties of instruction and examination assigned to him by the said regents, and shall receive a salary of $4,000 per annum, except that the chairman of the board shall receive a salary of $5,000 per annum.

"Sec. 3. The said regents shall also appoint, subject to appropriations by Congress, such minor offices, and shall establish such rules, regulations and forms as may be necessary to carry out the purposes of this act. They shall also establish a schedule of reasonable fees to be paid by candidates for examination for degrees, which fees shall be paid into the treasury of the United States to the credit of the Smithsonian Institution.

"Sec. 4. The said regents are hereby authorized to accept and to administer any bequest or gift of real or personal property which may be made to them to establish lectureships, to endow chairs of instruction, to establish fellowships, scholarships or prizes, to purchase land, to erect buildings, or otherwise to carry out the provisions of this act.

"Sec. 5. The sum of $50,000, or so much thereof as may be necessary, is hereby appropriated out of any monies in the treasury not otherwise appropriated, to be expended as other public monies appropriated for the use of the Smithsonian are expended to carry out the purposes of this act."

THE UNIVERSITY OF NEBRASKA.

At the December meeting of the Regents of the University of Nebraska, no election was made of a chancellor to fill the vacancy caused by the resignation of Dr. George MacLean, in July. The committee on chancellor asked for more time.

Dr. Bessey, acting chancellor, reported upon the condition of the University. Six hundred and twenty-two new students entered the University during the fall term, and at the present time there are registered in all departments 1560 students, this not including the students present in the summer session, nor those registered in the School of Music and School of Agriculture (short course). The total registration for the year will probably reach about 2100. The registrations in scientific work are as follows: Botany, 153; Chemistry, 526; Entomology, 25; Geology, 100; Physics, 348; Zoology, 160; in technical lines, Civil Engineering, 54; Electrical Engineering, 70; Mechanical Engineering, 251; in languages, German, 629; Greek, 172; Latin, 407; French, 328; English, 1556; History, 570; Political Science, 215; Law, 151.

Among the material improvements during the year are the steam tunnels for carrying steam heat to the different halls on the campus, the completion of the interior work on Mechanic Arts Hall, and the erection of 'Experiment Station Hall,' and an additional power plant—the two buildings last named being on the University Farm.

In accordance with a report made by a committee of the faculty, the regents designated exactly the constitution of the faculties of the two four-year colleges ('Letters' and 'Science').

On Acting Chancellor Bessey's recommendation, plans were ordered drawn with reference to the eventual removal of the University from its present site in the city to its domain in the suburbs known as the 'University Farm.' Early removal is not contemplated, but all buildings and other improvements on this domain are to be made hereafter with reference to the future removal of the University to its new site.

The acting chancellor called attention to the desirability of continuing the University work throughout the year, as is done in the University of Chicago, and the regents appointed a committee to investigate the matter and to report at a future meeting.

Dr. William W. Hastings was given a short leave of absence to enable him to make anthropometric investigations in northern Mexico. Professor Nicholson, for many years head professor of Chemistry, was given, on his request, a leave of absence for one year, beginning January 1, 1900. During his absence Dr. John White is head professor of the department.

RECENT ADDITIONS TO THE AMERICAN MUSEUM.

THE second portion of the Cope collection containing the Fishes, Amphibia and Reptilia has recently been acquired by the American Museum of Natural History as the munificent gift of President Jesup. It includes 350 described species, represented in the majority of cases by the type specimens. The Amphibian collection is from the Permian formation of Texas, and represents many years' work by Cummings and other collectors. There are also large numbers of primitive reptiles belonging to the Proganausauria and other groups. The Trias is fairly well represented, mainly from Pennsylvania. The Jura is represented by collections both from the Colorado Sandstones and from the Como Beds. The former are the most valuable and in the most complete condition, including, especially, the type of *Camarasaurus* and types of other genera which Professor Cope described but never worked up. The Kansas Cretaceous is represented by a very large collection of Mosasaurs and Pterosaurs in fairly good condition and including many of Cope's types. From the Laramie is an especially fine Hadrosaur, a complete skeleton of Diclonius capable of being mounted, also remains of the Ceratopsia. From other parts of the Mesozoic and from the Tertiary are a great variety of reptile remains more or less complete, including some fine Belodontia, Crocodilia and Chelonia. This supplements the very large reptilian collection already made by the American Museum which will now be worked up for the first time.

At the same time there has been presented to the Museum, by Messrs. Havemeyer, Iselin, Dodge, James and Osborn, the valuable Pampean collection purchased by Professor Cope at the Paris Exposition of 1878. This was the first large exhibition in Europe from the Argentine Republic; it includes several entire skeletons, especially those of the great sabre-tooth tiger, *Machærodus*, and of *Lestodon*, and parts of the skeleton of *Toxodon*, also the carapace of several of the armored Edentates. This collection was mounted for exhibition in Paris and very carefully packed at the time of its purchase by Professor Cope; it has never been unboxed since.

Dr. O. P. Hay, formerly of the Field Columbian Museum, who for some time past has been working in the National Museum, has accepted a position in the American Museum as Assistant Curator of Vertebrate Paleontology and will be especially engaged in the arrangement of the Cope Mesozoic collection; he will enter upon his duties January 15th.

SCIENTIFIC NOTES AND NEWS.

MR. G. K. GILBERT, of the U. S. Geological Survey, has been elected president of the American Association for the Advancement of Science, to fill the vacancy caused by the death of Professor Edward Orton.

WITH the close of the year, Assistant Charles A. Schott, who for nearly fifty years has been the distinguished and energetic chief of the Computing Division of the Coast and Geodetic Survey, retired from that important position in order to devote his whole time to special scientific work. Under Mr. Schott's careful supervision and training has developed a corps of skilled computers equalled by no other scientific bureau. To his labors, perhaps, more than to any other one man's, is due the high scientific character of the results which the Survey has given to the world. The completion last year of the great arc, begun over a quarter of a century ago, marks an epoch in the history of the Division, and, the beginning of the triangulation on the 98th meridian, would seem to be a fitting occasion for relieving Mr. Schott of the burden which he has borne for so many years. His official career has been coincident with the development of the Survey, and his untiring zeal and fidelity have done much to bring about its present standard. Assistant Schott will now devote himself to the discussion of the eastern oblique arc (Maine to Louisiana) and a similar arc in California. His successor is Assistant John F. Hayford, who for several months past has occupied the position of Inspector of Geodetic work, and has thus had general supervision, under the Superintendent's direction, of the field geodetic operations. His assumption of the duties of chief of the Computing Division in addition to his previous duties gives him the supervision of the geodetic operations from the inception of the plans and the beginning of the field work to the publication of the results, an arrangement which, doubtless, will be conducive to efficient coöperation of the field and office and to prompt publication of results. Mr. Hayford has had eight years' experience with the Survey both in field service and office work, and has, therefore, received excellent preparation for his present position.

INVITATIONS have now been sent for the memorial meeting in honor of the late Dr. Daniel Garrison Brinton, to be held in the hall of the Historical Society of Pennsylvania, Philadelphia, on Tuesday evening, January 16th. The American Philosophical Society issues the invitations on the part of

The University of Pennsylvania, The Academy of Natural Sciences, The Numismatic and Antiquarian Society, The Historical Society of Pennsylvania, The Geographical Society of Philadelphia, The Oriental Club of Philadelphia, Jefferson Medical College, The American Association for the Advancement of Science, The Smithsonian Institution, The Bureau of American Ethnology, The United States National Museum, The Anthropological Society of Washington, The American Folk-lore Society, The American Antiquarian Society, The New Jersey Historical Society, The New York Historical Society, The American Oriental Society, The Wyoming Historical and Geological Society, The Chester County Historical Society, The American Museum of Natural History, The Field Columbian Museum, The Peabody Museum of American Archæology and Ethnology, The Peabody Institute of Arts and Sciences, The Loyal Legion.

THE statue of Lavoisier, to be erected in Paris, will probably be unveiled in July of this year. The international subscription amounted to 98,000 francs.

SIR RICHARD THORNE THORNE, K.C.B., F.R.S., principal medical officer to the Local Government Board of England, and distinguished for his labors on behalf of public health, has died at the age of 58 years.

PRESIDENT MCKINLEY has designated the following officials to represent the United States Government at the International Medical Congress, which meets in Paris, in connection with the Exposition, August 2d, next, and to the congress of hygiene and demography, which assembles at the same place, August 10th: For the army Surgeon General Sternberg and Surgeon LaGarde; for the navy, Surgeon General Van Reypen; for the marine hospital service, Surgeon General Wyman and Passed Assistant Surgeon Rosenau.

MR. FRANK LENEY, of the Geological Department of the British Museum, has been appointed assistant curator of the Norwich Museum.

DR. LABOURAND has been appointed director of a laboratory newly established by the Municipal Council of Paris, his chief duties being to make inspections of the city schools with a view to diseases of the skin.

THE position of chemist, New York State Board of Health, will be filled on or about January 27th. The examination will consist entirely of practical questions relating to analysis of food products and questions relating to experience and training of the candidates.

AT a meeting of the American Ethnological Society, held December 19th, at the American Museum of Natural History, the following officers were elected for the ensuing year:

President, Mr. Morris K. Jesup; *First Vice-President*, General Grant Wilson; *Second Vice-President*, Professor Franz Boas; *Recording Secretary*, Livingston Farrand; *Corresponding Secretary*, Marshall H. Saville; *Treasurer*, Mr. Frederick Hyde, Jr.

THE Australasian Association for the Advancement of Science is holding its annual meeting this week at Melbourne, under the presidency of Mr. R. L. J. Ellery.

THE eighth International Geological Congress will be held in Paris from August 16th to 26th. The sessions will be divided into four sections, as follows: (1) General and technical geology; (2) stratigraphy and paleontology; (3) mineralogy and petrography; (4) economic geology and hydrography.

THE New York State Museum has recently acquired from Mr. C. J. Sarle an interesting collection of several hundred specimens representing a new crustacean fauna from dark shales at the base of the Salina beds of western New York. These contain numerous species of the merostoms *Eurypterus Pterygotus* and other genera, which have not before been observed.

THE German Imperial Government will contribute an annual subsidy of $5,000 toward the

Institute of Tropical Hygiene, to be opened at Hamburg on October 1st.

MR. MARSHALL H. SAVILLE left New York on December 22d for Mexico to conduct archæological investigations for the department of anthropology of the American Museum of Natural History.

PROFESSOR FREDERICK STARR, of the University of Chicago, is on an exploring trip in Mexico to continue his anthropological researches.

REUTER'S AGENCY announces that the expedition of Baron Toll, organized for the exploration of the New Siberia Islands and Sannikoff Land, to which no man has yet penetrated, will set out in June next from a Norwegian port, whence it will proceed to the mouth of the Lena, on the banks of which river, at a point above the town of Yakutsk, it will pass the winter. During the summer of 1901 the expedition will begin its explorations towards the north, picking up *en route* a detachment which will be sent forward from the main body during March, with a sufficient supply of dogs.

THE Smithsonian Institution has issued a catalogue of its publications available for distribution in December, 1899. The catalogue can probably be obtained on application, and should be in the hands of men of science, as many valuable papers, reprints and monographs can be secured at a comparatively small price.

THE publishers, MM. Georges Carré and C. Naud, 3 rue Racine, Paris, propose to issue an *Annuaire des Mathématiciens*, containing the names, addresses, etc., of all who are engaged in studying or teaching mathematics. The publishers ask the coöperation of all mathematicians, who are requested to forward their names and addresses.

Nature reports that the Brussels Academy of Sciences has awarded the prize of six hundred francs, for an important contribution to geometry, to M. Léon Autonne, of the University of Lyons. The prize of six hundred francs for anatomical and systematic investigations of insects of the group Apterygota (Thysanura and Collembola) has been awarded to M. Victor Willem, of the University of Ghent. M. F. Keelhoff, of the same University, has been awarded the Prix Charles Lemaire (interest on twenty-five thousand francs) for a work entitled 'Note sur le travail des forces élastiques.' The decennial prize of five thousand francs for botanical science has been awarded to Professor Alfred Cogniaux; and a prize of the same value for chemistry and physics has been given to Professor Louis Henry. To fill vacancies caused by death, the Academy has elected as foreign associates in the section of mathematics and physics, Sir G. G. Stokes, Professor Moissan and Professor Jordan. In the section of natural sciences, M. C. Vanlair has been elected a *membre titulaire*, Professors Pelseneer and Gravis have been elected correspondents, and Sir John Murray and M. Maupas have been elected associates.

THE Berlin correspondent of the London *Times* states that the plan and details are now published of the vessel which is being built at the Howaldt Shipbuilding Yard at Kiel for the German Antarctic expedition. The ship in question will be built of wood, the only material strong and elastic enough to resist the pressure of the ice. In form she will be somewhat rounder than the *Fram*, and will not fall away towards the keel in the same manner. It will be remembered that at the Geographical Congress in Berlin, Dr. Nansen himself expressed the opinion that the shape of the *Fram* would not be suitable for the heavy weather of the southern seas. In order to strengthen the ship against the pressure of the ice, the middle deck will be built very nearly on the level of the water-line. Protection against floating ice will be afforded by a triple coating of oak, pitch-pine and South American greenwood, and the bow and stern will be especially protected by steel bands. The length of the ship will be about 46 meters, the breadth between 10 and 11 meters, and the draught about five meters. She will be constructed to carry coal and other stores sufficient for three years, and will contain accommodation for five scientific observers, five officers and a crew of about 20 men. Each of the scientific travelers and each of the officers will have his own cabin. Four rooms will be assigned to the crew. The engine and the boiler will be placed in the stern, between the living rooms. The center of the ship will be occupied by the rooms for scientific work and the forecastle will contain space for 50 Arctic dogs. The ship will be rigged as a three-masted schooner. Two steam winches will serve the anchor and will also be used for scientific purposes. The ship will be illuminated throughout with electric light. The Howaldt Shipbuilding Yard, which is under a contract to have the ship built by the 1st of May, 1901, and fitted out not later than the end of August, 1901, has already begun the construction. A model of the vessel will be shown at the Paris Exhibition.

LECTURES given or about to be given before the Royal Institution, London, are as follows: Mr. C. Vernon Beys, six Christmas lectures (specially adapted for young people) on Fluids in motion and at rest; Professor E. Ray Lankester, twelve lectures on the Structure and classification of fishes; Dr. W. H. R. Rivers, three lectures on the Senses of primitive man; Professor H. H. Turner, three lectures on Moddern astronomy; Dr. Charles Waldstein, three lectures on Recent excavations at Argive Heræum (in Greece), three lectures by Sir Hubert H. Parry; Mr. W. L. Courtney, three lectures on the Idea of tragedy in ancient and modern drama; the Right Hon. Lord Rayleigh, six lectures on Polarized light. The Friday evening meetings will begin on January 19th, when a discourse will be given by the Right Hon. Lord Rayleigh, on Flight; succeeding discourses will probably be given by the Hon. C. A. Parsons, Professor J. Reynolds Green, Mr. H. Warrington Smyth, Professor J. H. Poynting, Major Ronald Ross, Professor Frank Clowes, Sir Benjamin Stone, M.P., Professor J. Arthur Thomson, Sir A. Noble, Professor Dewar and others.

UNIVERSITY AND EDUCATIONAL NEWS.

MR. JOHN D. ROCKEFELLER has given $100,000 to Columbia University to endow the chair of psychology.

MR. ANDREW CARNEGIE has given $300,000 to Cooper Union, New York City, and $200,000 has been contributed by Abram S. Hewitt and Mr. Edward Cooper. This will enable the Union to establish courses in mechanic arts.

SYRACUSE UNIVERSITY receives $25,000 by the will of the late Erastus F. Holden, of Syracuse.

THE Italian Parliament has voted a sum of 1,300,000 lire for the erection of new buildings for the University of Bologna.

PRESIDENT J. M. CRAFTS, of the Massachusetts Institute of Technology, has presented his resignation, to take effect at the close of the present academic year. In his letter of resignation, he says: "My reasons for taking this step at the time are founded upon my desire to return to purely scientific occupations. My term in office has shown me the wide field of educational problems, both within and outside the Institute, which should be studied, and I have found that such studies and the performance of administrative duties, although not in themselves burdensome, leave little freedom for the pursuit of experimental science. A choice must be made between administrative and scientific occupations, and it is the latter which I wish to choose."

EDWIN GRANT DEXTER, A.M. (Brown), Ph.D. (Columbia), now of the State Normal College, Greeley, Colo., has been elected professor of pedagogy in the University of Illinois.

MR. E. M. BLAKE, Ph.D., who was recently elected to an honorary fellowship in mathematics at Cornell University, has entered upon his work there. Mr. Blake received his doctor's degree from Columbia University in 1893, after which he spent two years there as instructor in Barnard College. He spent the year '95–'96 as a student in Leipzig, Berlin and Göttingen, and in '96–'98 was instructor in mathematics in Purdue University. Since leaving Purdue, Dr. Blake has been a student in Paris; his investigations thus far have been chiefly in kinematics.

BY a recent Ministerial decree, M. Sergejevich, whose unpopularity with the students of the University of St. Petersburg is said to have been one of the chief causes of the disturbances that have occurred among them, has been relieved of his functions as Rector of the University of St. Petersburg. He has been succeeded by Professor Holmstein, who is credited with liberal tendencies.

MSS. intended for publication and books, etc., intended for review should be sent to the responsible editor, Professor J. McKeen Cattell, Garrison-on-Hudson, N. Y.

THE CENTURY'S PROGRESS IN APPLIED MATHEMATICS.

II.

ANOTHER question of widely general, and of peculiar mathematical interest, is the problem first attacked by Fourier, of the distribution and consequent effects of the earth's internal heat. The most interesting phase of this question is that which relates to the time that has elapsed since the crust of the earth became stable and sufficiently cool to support animal life. It is now nearly forty years since Lord Kelvin* startled geologists especially by telling them that Fourier's theory of heat conduction forbids anything like such long intervals of time as they were in the habit of assigning to the aggregate of paleontological phenomena. On several occasions since then Kelvin has restated his arguments with a cogency that has silenced most geologists if it has not convinced most mathematicians. Quite recently, however, the question has become somewhat less one-sided, since geologists and paleontologists are beginning to defend their positions† while that of

*In a memoir 'On the secular cooling of the earth,' *Trans. Royal Society of Edinburgh*, 1862. Republished in Kelvin and Tait's Treatise on Natural Philosophy, appendix D. Kelvin's latest paper on this subject is entitled 'The age of the earth as an abode fitted for life,' and is published in *Philosophical Magazine*, January, 1899; also in SCIENCE, May 12, 1899.

† See Professor T. C. Chamberlin's paper, "Lord

Kelvin is being attacked from the mathematical side.* My own views on this subject were expressed somewhat at length ten years ago, in the address already referred to, and it seems unnecessary here to go into the matter any further than to reaffirm my conviction that the geologists have adduced the weightier arguments. Beautiful as the Fourier analysis is, and absorbingly interesting as its application to the problem of a cooling sphere † is, it does not seem to me to afford anything like so definite a measure of the age of the earth as the visible processes and effects of stratification to which the geologists appeal. In short, the only definite results which Fourier's analysis appears to me to have contributed to knowledge concerning the cooling of our planet are the two following, namely: first, that the process of cooling goes on so slowly that nothing less than a million years is a suitable time unit for measuring the historical succession of thermal events; and secondly, that this process of cooling goes on substantially as if the earth possessed neither oceans nor atmosphere.

It was the well-founded boast of Laplace in the early part of the century that astronomy is the most perfect of the sciences;* and expert contemporary opinion, as we have seen in the case of no less a personage than Green, agreed that the 'Mécanique Céleste' left little room for further advances. Indeed, it would appear that the completeness and the brilliancy of the developments of celestial dynamics during the half century ending with 1825 (the period of Laplace's activity) completely overshadowed all other sciences and retarded to some extent the progress of astronomy itself. The stupendous work of Laplace was chiefly theoretical, however, and he was content in most cases with observational data which accorded with theory to terms of the first order of approximation only. He was probably not so profoundly impressed as men of science at this end of the century are with the necessity of testing a theory by the most searching observational means available. In fact, in elaborating his methods and in applying his theories to the members of the solar system, it has been essential for his disciples to display a degree of ingenuity and a persistence of industry worthy of the master himself. But the prerequisite to progress in celestial mechanics consisted not so much in following up immediately the lines of investigation laid down by Laplace, as in perfecting the methods and in increasing the data of observational astronomy.

Kelvin's address on the age of the earth as an abode fitted for life,' SCIENCE, June 30, 1899; also Sir Archibald Geikie's presidential address to Geological Section of the British Association for the Advancement of Science, Dover meeting, 1899.

* Notably by Professor John Perry. See *Nature*, January 3, and April 18, 1895.

† I have recast this problem of Fourier in two papers published in the *Annals of Mathematics*, Vol. III., pp. 75–88 and pp. 129–144. The solution there given is the only one, so far as I am aware, which lends itself to computation for all values of the time in the history of cooling. A point of much mathematical interest on which this solution depends is the equivalence of the two following series:

$$ru = \frac{2r_0u_0}{\pi}\sum_{n=1}^{n=\infty}\left(\frac{-1}{n}\right)^{n+1} e^{-a^2(n\pi/r_0)^2t}\sin n\pi\frac{r}{r_0},$$

$$= ru_0 - \frac{2r_0u_0}{\sqrt{\pi}}\sum_{n=0}^{n=\infty}\int_{(2n+1)m_0-m}^{(2n+1)m_0+m} e^{-z^2}dz.$$

In these u is the temperature at a distance r from the center of the sphere at any time t; u_0 is the initial uniform temperature of the sphere; r_0 is the radius of the surface of the sphere; a^2 is the diffusivity, supposed constant; and $m = r/(2\sqrt{t})$, $m_0 = r_0/(2a\sqrt{t})$. It will be observed that when the first series (which is Fourier's) converges very slowly, the second converges very rapidly, and vice versa. It will be seen also, that the series refuse, as they should, to give values of the temperature corresponding to negative values of the time.

* "L'Astronomie, par la dignité de son objet et par la perfection de ses théories, est le plus beau monument de l'esprit humain, le titre le plus noble de son intelligence." Système du Monde, Ed., 1884, p. 486.

The development of this branch of science along with the development of the closely related science of geodesy, is a work essentially of the present century, and must be attributed chiefly to the German school of astronomers led by Gauss and Bessel. It is to these eminent minds, as well known in pure as in applied mathematics, that we are indebted for the theories, and for the most advantageous methods of use, of instrumental appliances, and for the refined processes of numerical calculation which secure the best results from observational data. It is a fortunate circumstance, perhaps, considering the irreverence which some modern pure mathematicians show for numerical computations, that Gauss and Bessel began their careers long before the resistless advent of the theory of functions and the theory of groups.

The story of the opportune discovery of the planet Ceres, as related by Gauss himself in the preface to his Theoria Motus Corporum Cœlestium, is well known; but it is less well known that the merit of this magnificent work lies rather in the model groups of formulas presented for the precise numerical solution of intricate problems than in the facility afforded for locating the more obscure members of the solar system. Indeed, the works of Gauss and Bessel are everywhere characterized by a clear recognition of the important distinction between those solutions of problems which are, and those which are not, adapted to numerical calculation. They showed astronomers how to systematize, to expedite, and to verify arithmetical operations in ways which were alone adequate to the accomplishment of the vast undertakings which have since been completed in mathematical geodesy and in sidereal astronomy.

Among the most important contributions of these authors to geodesy and astronomy in particular, and to the precise observational sciences in general, is that branch of the theory of probability called the 'method of least squares.'* No single adjunct has done so much as this to perfect plans of observation, to systematize schemes of reduction, and to give definiteness to computed results. The effect of the general adoption of this method has been somewhat like the effect of the general adoption by scientific men of the metric system; it has furnished common modes of procedure, common measures of precision, and common terminology, thus increasing to an untold extent the availability of the priceless treasures which have been recorded in the century's annals of astronomy and geodesy.

When we pass from the field of observational astronomy to the more restricted but more intricate field of dynamical astronomy, it is apparent that Laplace and his contemporaries quite underestimated the magnitudes of the mathematical tasks they bequeathed to their successors. Laplace, almost unaided, had performed the unparalleled feat of laying down a complete outline of the 'system of the world'; but the labor of filling in the details of that outline, of bringing every member of the solar system into harmony at once with the simple law of gravitation and with the inexorable facts of observation, is a still greater feat which has taxed the combined efforts of the most acute analysts and the most skillful computers of the preceding and present generation.

It is impossible within the limits of a semi-popular address to do more than mention in the most summary way the extraordinary contributions to dynamical astronomy made especially during the present

* Gauss's fundamental paper in this subject is "Theoria combinationis observationum erroribus minimis obnoxiæ," and dates from 1821. Werke, Band IV.

Bessel's numerous contributions to this subject are found in his "Abhandlungen" cited above.

half century, contributions alike formidable by reason of their bulk and by reason of the complexity of their mathematical details. An account of the theory of the perturbative function, or of the theory of the moon, for example, would alone require space little short of a volume.* To mention only the most conspicuous names, there is the pioneer and essentially prerequisite work of the illustrious Gauss and the incomparable Bessel. There is the remarkable work of the brilliant Leverrier (1811–1877), and the not less brilliant Adams (1819–1892),† well known to popular fame by reason of what may be called their mathematical discovery of the planet Neptune. Then came the monumental 'Tables de la Lune' ‡ from the arithmetical laboratory of the indefatigable Hansen; and this marvellous production was quickly followed (1860) by the equally ponderous, and mathematically more important, 'Théorie du Mouvement de la Lune'§ from the pen of the admirably fertile and industrious Delaunay. And finally, there is the still more elaborate work, bringing this great problem of the solar system well-nigh to completeness of solution, which, by common consent, is credited to the two preceding presidents of the American Mathematical Society. || Probably no mathematico-physical undertakings of the century have yielded so many definite, quantitative results to the permanent stock of knowledge as the researches in dynamical astronomy.

*A good account of the progress in dynamical astronomy from 1842 to 1867 is given by Delaunay in 'Rapport sur les Progrès de l'Astronomie,' Paris, 1867.

† The papers of Adams have been edited by Professor W. G. Adams and supplied with a biographical memoir by Professor J. W. L. Glaisher, under the title 'Scientific Papers of John Couch Adams,' Cambridge, at the University Press, Vol. I., 1896.

‡ Published by the British government in 1857.

§ *Mémoires de l'Académie des Sciences de l'Institut Impérial de France,* Tomes XXVIII., XXIX.

|| For an account of the more recent work of Gyldén and Poincaré, reference is made to the presidential address of Dr. G. W. Hill, "Remarks on the progress of celestial mechanics since the middle of the century"; *Bulletin American Mathematical Society,* 2d series, Vol. II., No. 5, p. 125.

But notwithstanding the astonishing degree of perfection to which this science has been brought, there are still some outstanding discrepancies which indicate that the end of investigation is yet a long way off. The moon, which has given astronomers as well as other people, more trouble than any other member of the solar system, is still devious to the extent of a few seconds in a century. The earth, also, it is suspected, is irregular as a time-keeper by a minute but sensible amount;* while it has been proved recently by the exquisite precision of modern observations, that the earth's axis of rotation wanders in a complex way through small but troublesome angles from its mean position, thus causing variations in the astronomical latitude of a place.†

* The effect of tidal friction on the speed of rotation of the earth appears to have been first explained by Ferrel in a 'Note on the influence of the tides in causing an apparent acceleration of the moon's mean position.' This paper was read before the American Academy of Arts and Sciences, in December, 1864, only a few weeks before Delaunay read a similar paper before the French Academy. See Ferrel's autobiography cited above. See also Delaunay's account of his own work in 'Rapport sur les progrès de l' astronomie,' Paris, 1867.

† The cause of such variations is found in the relative mobility of the parts of the earth, especially in the mobility of the oceans and atmosphere. Three types of variation may occur, namely: 1st, that due to sudden changes in the relative positions of the parts of the earth's mass; 2d, that due to secular changes in position of those parts; and 3d, that due to periodic shiftings of those parts. Of these the most important appears to be the periodic type. A surprising, and as yet not fully explained, discrepancy brought to light by the discovery of latitude variations is the fact that the instantaneous axis of rotation of the earth makes a complete circuit around the axis of figure in about 428 days, instead of in about 305 days as has been supposed from the time of Euler down to the present decade. The discovery of this discrepancy is due to

A question of intense interest to astronomers in the early part of the century is that of the stability of the solar system. Lagrange, Laplace, and Poisson thought they had demonstrated that, whatever may have been the origin of this system, the existing order of events will go on indefinitely. This conclusion seems to have been alike satisfactory to scientific and unscientific men. But with the growth of the doctrine of energy and with the developments of thermodynamics, it has come to appear highly probable that the solar system has not only gone through a long series of changes in the past, but is destined to undergo a similarly long series of vicissitudes in the future. In other words, while our predecessors of a century ago thought the 'system of the world' stable, our contemporaries are forced to consider it unstable.*

But interesting as this question of stability still is, there is no pressing necessity, fortunately, for a determination of the ulterior fate of our planet. A more important question lies close at hand, and merits, it seems to me, immediate and serious investigation. This question is the fundamental one whether the beautifully simple law of Newtonian attraction is exact or only approximate. No one familiar with celestial mechanics or with the evidence for the law of gravitation as marshalled by Laplace in his 'Système du Monde' can fail to appreciate the reasons for the profound conviction, long held by astronomers, that this law is exact. But on the other hand no one acquainted with the obstinate properties of matter can now be satisfied with the Newtonian law until it is proved to hold true to a much higher degree of approximation than has been attained hitherto.* For, in spite of the superb experimental investigations made particularly during the past quarter of a century by Cornu and Baille,† Poynting,‡ Boys,§ Richarz and Krigar-Menzel,|| and Braun,¶ it must be said that the gravitation constant is uncertain by some units in the fourth significant figure, and possibly by one or two units even in the third figure;** thus falling, along with the sun's parallax, the annual stellar aberration, and the moon's mass, amongst the least well determined constants of the solar system. Here then is a fruitful field for research. The direct measurement of the gravitation constant to a much higher degree of precision seems to

Dr. S. C. Chandler and was announced in the *Astronomical Journal*, No. 248, November, 1891. For the mathematical theory of this subject and for titles of the principal publications bearing on this theory, reference may be made to the author's paper on 'Mechanical interpretation of variations of latitudes,' *Astronomical Journal*, No. 345, May, 1895; and to a paper by S. S. Hough on 'The rotation of an elastic spheroid,' *Philosophical Transactions*, No. 187, 1896.

* See a review of this subject by M. H. Poincaré, "Sur la stabilité du système solaire," in *Annuaire du Bureau des Longitudes*, for 1898.

* As to the degree of precision with which the Newtonian law is established by astronomical data, see Professor Newcomb's "Elements of the four inner planets and the fundamental constants of astronomy," Supplement to American Ephemeris and Nautical Almanac for 1897, Washington, 1895.

† *Comptes rendus*, LXXVI., 1873.

‡ The Mean Density of the Earth, by J. H. Poynting, Chas. Griffin & Co., London, 1894.

§ *Philosophical Transactions*, No. 186, 1895.

|| Sitzungsberichte, Berlin Academy, Band 2, 1896.

¶ *Denkschriften*, Math. Natur. Classe, Vienna Academy, Band LXIV., 1897.

** The results of the investigators mentioned for the gravitation constant are, in C. G. S. units, as follows, the first result having been computed from data given by MM. Cornu and Baille in the publication referred to:

Cornu and Baille (1873)	6668×10^{-11}
Poynting (1894)	6698×10^{-11}
Boys (1894)	6657×10^{-11}
Richarz and Krigar-Menzel (1896)	6685×10^{-11}
Braun (1897)	6658×10^{-11}

Regarding these as of equal weight, their mean is 6673×10^{-11} with a probable error of ± 5 units in the fourth place, or 1/1330th part. This is of about the same order of precision as that deduced by Professor Newcomb from astronomical data.

present insuperable obstacles ; but may not the result be reached by indirect means, or may it not be possible to make the solar system break its Sphinx-like reticence of the centuries and disclose the gravitational mechanism itself?

Just as the theories of astronomy and geodesy originated in the needs of the surveyor and navigator, so has the theory of elasticity grown out of the needs of the architect and engineer. From such prosaic questions, in fact, as those relating to the stiffness and the strength of beams, has been developed one of the most comprehensive and most delightfully intricate of the mathematico-physical sciences. Although founded by Galileo, Hooke, and Mariotte in the seventeenth century, and cultivated by the Bernoullis and Euler in the last century, it is, in its generality, a peculiar product of the present century.* It may be said to be the engineer's contribution of the century to the domain of mathematical physics, since many of its most conspicuous devotees, like Navier, Lamé, Rankine, and Saint-Venant, were distinguished members of the profession of engineering; and it is a singular circumstance that the first of the great originators in this field, Navier, should have been the teacher of the greatest of them all, Barré de Saint-Venant. † Other great names are also prominently identified with the growth of this theory and with the recondite problems to which it has given rise. The acute analysts, Poisson, Cauchy, and Boussinesq, of the French school of elasticians ; the profound physicists, Green, Kelvin, Stokes, and Maxwell, of the British school; and the distinguished Neumann (Franz Ernst, 1798–1895), Kirchhoff (1824-1887), and Clebsch (1833–1872), of the German school; have all contributed heavily to the aggregate of concepts, terminology, and mathematical machinery which make this at once the most difficult and the most important of the sciences dealing with matter and motion.

The theory of elasticity has for its object the discovery of the laws which govern the elastic and plastic deformation of bodies or media. In the attainment of this object it is essential to pass from the finite and grossly sensible parts of media to the infinitesimal and faintly sensible parts. Thus the theory is sometimes called molecular mechanics, since its range extends to infinitely small particles of matter if not to the ultimate molecules themselves. It is easy, therefore, considering the complexity of matter as we know it in the more elementary sciences, to understand why the theory of elasticity should present difficulties of a formidable character and require a treatment and a nomenclature peculiarly its own.

While it would be quite inappropriate on such an occasion to go into the mathematical details of this subject, I would recall your attention for a moment to the surprisingly simple and beautiful concepts from which the mathematical investigation proceeds rapidly and unerringly to the equations of equilibrium or motion of a particle of any medium. The most important of these are the concept which relates to the stresses on the particle arising from its connection with adjacent parts of the medium, and

* An admirable history of this science, dealing with its technical aspects, was projected by Professor Isaac Todhunter and completed by Professor Karl Pearson, under the title "A History of the Theory of Elasticity and the Strength of Materials from the time of Galilei to the present time." Cambridge, at the University Press: Vol. I., Galilei to Saint-Venant, 1886; ol. VII., Parts I. and II., Saint-Venant to Lord Kelvin, 1893.

A capital though abridged history of the science is given by Saint-Venant in his annotated edition of Navier's Résistance des Corps Solides, troisième édition, Paris, 1864.

The history of Todhunter and Pearson is dedicated to Saint-Venant, who has been fitly called 'the dean of elasticians.'

† And this illustrious master has left a worthy pupil in M. J. Boussinesq, Professor in the Faculty of Sciences, Paris.

the concept with regard to the distortions of the particle which result from the stresses. If the particle be a rectangular parallelopiped, for example, these stresses may be represented by three pressures or tensions acting perpendicularly to its faces together with three tensions acting along, or tangentially to, those faces. Thus the adjacent parts of the medium alone contribute six independent force components to the equations of equilibrium or motion; and the stresses, or the amounts of force per unit area, which produce these components are technically known as tractions or shears according as they act perpendicularly to or tangentially along the sides of the particle.* Corresponding to these six components there are six different ways in which the particle may undergo distortion. That is, it may be stretched or squeezed in the three directions parallel to its edges; or, its parallel faces may slide in three ways relatively to one another. These six different distortions, which lead in general to a change in the relative positions of the ends of a diagonal of the parallelopiped, are measured by their rates of change, technically called strains, and distinguished as stretches or slides according as they refer to linear or angular distortion.†

It is from such elementary dynamical and kinematical considerations as these that this theory has grown to be not only an indispensable aid to the engineer and physicist, but one of the most attractive fields for the pure mathematician. As Pearson has remarked, "There is scarcely a branch of physical investigation, from the planning of a gigantic bridge to the most delicate fringes of color exhibited by a crystal, wherein it does not play its part."* It is, indeed, fundamental in its relations

* The terminology here used is that of Todhunter and Pearson, History of the Theory of Elasticity and Strength of Materials, Vol. I., Note B.

† The terminology and symbology of the theory of elasticity appear to be more highly developed than those of any other mathematical science. A comparison of the terms and symbols of elasticity with those of the older subject of hydromechanics, as shown, in part, below, is instructive:

IN ELASTICITY.

Stresses.		Strains.	
Tractions	p_{xx}, p_{yy}, p_{zz}	Stretches	s_x, s_y, s_z
Shears	p_{yz}, p_{zx}, p_{xy}	Slides	σ_{yz}, σ_{zx}, σ_{xy}

Shifts, or components of displacement: u, v, w

Shift-fluxions, or space rates of change of shifts: $\frac{\partial u}{\partial x}, \frac{\partial u}{\partial y}, \frac{\partial u}{\partial z}$, $\frac{\partial v}{\partial x}$, etc., $\frac{\partial w}{\partial x}$, etc.,

Dilitation, $\theta = s_x + s_y + s_z = \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z}$

Twists:
$$\tau_{yz} = \frac{1}{2}\left(\frac{\partial w}{\partial y} - \frac{\partial v}{\partial z}\right),\quad \tau_{zx} = \frac{1}{2}\left(\frac{\partial u}{\partial z} - \frac{\partial w}{\partial x}\right),\quad \tau_{xy} = \frac{1}{2}\left(\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y}\right)$$

to the theory of structures, to the theory of hydromechanics, to the elastic solid theory of light, and to the theory of crystalline media.

In closing these very inadequate allusions to this intensely practical and abstrusely mathematical science, it is fitting that attention should be called to the magnificent labors of the 'dean of elasticians,' M. Barré de Saint-Venant. It was the object of his life-work to make the theory of elasticity serve the utilitarian purposes of the engineer and at the same time to divest it so far as possible of all empiricism. His epoch-making memoir* of 1853, on the torsion of prisms, is not only a classical treatise from the practical point of view, but one of equal interest and importance in its theoretical aspects. His investigations are everywhere delightfully interesting and instructive to the physicist; and many parts of them are replete, as observed by Kelvin and Tait,† with "astonishing theorems of pure mathematics, such as rarely fall to the lot of those mathematicians who confine themselves to pure analysis or geometry, instead of allowing themselves to be led into the rich and beautiful fields of mathematical truth which lie in the way of physical research." More important still in a didactic sense are his annotated edition of Navier's 'Résistance des Corps Solides,' of 1864, and his annotated edition of the French translation of the 'Theorie der Elasticität fester Körper,' of Clebsch, which appeared in 1883. These monumental works, whose annotations and explanatory notes quite overshadow the text of the original authors, must remain for a long time standard sources of information as to the history, theory, methods and results of this complex subject. The luminous exposition, the penetrating insight into physical relations, and the scientific candor in his criticism of other authors, render the work of Saint-Venant worthy of the highest admiration.

Closely allied to the theory of elasticity, though historically much older, is the science of hydromechanics. The latter is, indeed, included essentially in the former; and probably the great treatises of the next century will merge them under the title of molecular mechanics. It may seem somewhat singular that the mathematical theory of solids should have originated so many centuries later than the theory of fluids; for at first thought, tangible though flexible solids would appear much more susceptible of investigation than mobile liquids and invisible gases. But a little reflection leads one to the conclusion that it was, in fact, much easier to observe the data essential to found a theory of hydromechanics than it was to discover the principles which led to the theory of stress and strain; and the time interval between Archimedes and Galileo may serve perhaps as a rough measure of the relative complexity of hydrostatics and the theory of flexure and torsion of beams. It must not be inferred, however, that the simplicity of the phenomena of fluids in a state of relative rest extends to the phenomena of fluids in a state of relative motion; for the gap that separates hydrostatics from hydrokinetics is one which has not yet been fully bridged even by the aid of the powerful resources of modern mathematics.

The elements of hydrokinetics, with which branch of hydromechanics this sketch is alone concerned, were laid down by Euler about the middle of the last century.* It

is to him that we owe the equations of motion of a particle of a 'perfect fluid.' This is an ideal fluid, moving without friction, or subject, in technical terminology, to no tangential stress. But while no such fluids exist, it is easily seen that under certain circumstances this assumed condition approaches very closely to the actual condition; and, in accordance with the method of mathematico-physical science in untangling the intricate processes of nature, progress has proceeded by successive steps from the theory of ideal fluids toward a theory of real fluids.

The history of the developments of hydromechanics during this century has been very carefully and completely detailed in the reports to the British Association for the Advancement of Science of Sir George Gabriel Stokes,* in 1846, and of Professor W. M. Hicks,† in 1881 and 1882. And the history of the subject has been brought down to the present time by the address of Professor Hicks before Section A of the British Association for the Advancement of Science in 1895, and by the report‡ of Professor E. W. Brown to Section A of the American Association for the Advancement of Science in 1898. It may suffice here, therefore, to glance rapidly at the salient points which mark the advances from the state of the science as it was left by Lagrange a hundred years ago.

The general problem of the kinetics of a particle of a 'perfect fluid' is easily stated. It is this:* given for any time and for any position of the particle its internal pressure, its density, and its three component velocities, along with the forces to which it is subject from external causes; to find the pressure, density, and velocity components corresponding to any other time and to any other position. There are thus, in general, five unknown quantities requiring as many equations for their determination. The usual six equations of motion, or the equations of d'Alembert, contribute only three to this required number, namely, the three equations of translation of the particle, since the three which specify rotation vanish by reason of the absence of tangential stress. A fourth equation comes from the principle of the conservation of mass, which is expressed by equating the time rate of change of the mass of the particle to zero. This gives what is technically called the equation of continuity. A fifth equation is usually found in the law of compressibility of the fluid considered.†

Now, the equations of rotation, as just stated, refuse to answer the question whether the particles proceed in their

Reference should be made also to Professor A. E. H. Love's paper 'On recent English researches in vortex-motion,' in the *Mathematische Annalen*, Band XXX., 1887.

* The statement here given is that of the 'historical method,' which seeks to follow a particle of fluid from some initial position to any subsequent position and to specify its changes of pressure, density and speed. What is known as the 'statistical method,' on the other hand, directs attention to some fixed volume in the fluid and specifies what takes place in that volume as time goes on.

† The five equations in question are

$$\frac{du}{dt}=X-\frac{1}{\rho}\frac{\partial p}{\partial x},\qquad \frac{d(V\rho)}{dt}=0,$$
$$\frac{dv}{dt}=Y-\frac{1}{\rho}\frac{\partial p}{\partial y},$$
$$\frac{dw}{dt}=Z-\frac{1}{\rho}\frac{\partial p}{\partial z},\qquad p=f(\rho);$$

in which p is the pressure and ρ is the density at the centroid (x, y, z) of the particles; V is its volume; u, v, w are its component velocities; and X, Y, Z are the force components per unit mass arising from external causes.

orbits without rotation or whether they undergo rotation along with their motion of translation. This was a critical question, for the failure to press and to answer it seems to have retarded progress for nearly half a century. Lagrange, and after him Cauchy and Poisson, knew that under certain conditions* the differential equations of motion are integrable, but they do not appear to have understood the physical meaning of these conditions. It remained for Sir George Gabriel Stokes to show that the Lagrangian conditions of integrability correspond to the case of no molecular rotation, thus clearly distinguishing the two characteristic types of what we now call irrotational and rotational motion.† Such was the great step made by Stokes in 1845; and it furnishes a forcible illustration of the importance, in applied mathematics, of attending to the physical meaning of every symbol and every combination of symbols.

Thirteen years later came the remarkable memoir of Helmholtz (1821–1894) on the integrals of the equations of hydrokinetics for the case of rotational, or vortex, motion.‡ This memoir is alike wonderful for the directness with which the mathematical argument proceeds to its conclusions and for the clearness of insight it affords of the physical phenomena discussed. In short, it opened up a new realm and supplied the results, concepts, and methods which led the way to the important advances in the science made during the past three decades.

Another powerful impulse was given to hydrokinetics, and to all other branches of mathematical physics as well, by Kelvin and Tait's Natural Philosophy—the Principia of the nineteenth century—the first edition of which appeared in 1867. From this great work have sprung most of the ideas and methods appertaining to the theory of motion of solids in fluids, a theory which has yielded many interesting and surprising results through the researches of Kirchhoff, Clebsch, Bjerknes, Greenhill, Lamb and others. Of prime importance also are the numerous contributions of Lord Kelvin to other branches of hydrokinetics, and particularly to the theory of rotational motion.* In fact, every department of the entire science of hydromechanics, from the preliminary concepts up to his vortex atom theory of matter, has been illuminated and extended by his unrivalled fertility.

When we turn to the more intricate branch of the subject which deals with the motion of viscous fluids, or with the motion of solids in such fluids, it appears that the progress of the century is less marked, but still very noteworthy. This branch is closely related to the theory of elasticity, and goes back naturally to the early researches of Navier, Poisson and Saint-Venant; but the revival of interest in this, as well as in the less intricate branch of the subject, seems to date from the fruitful memoir† of Stokes, of 1845, and from his report to the British Association for the Advancement of Science of 1846. Since then many interesting and useful problems relative to the flow of viscous fluids and to

* That is, when $udx + vdy + wdz$ is a perfect differential, u, v, w being velocity components; or, when

$$\frac{\partial w}{\partial y} - \frac{\partial v}{\partial z}, \quad \frac{\partial u}{\partial z} - \frac{\partial w}{\partial x}, \quad \frac{\partial v}{\partial x} - \frac{\partial u}{\partial x},$$

which are the doubles of the components of molecular rotation, vanish, these latter being the conditions for the existence of a velocity potential.

† This discovery of Stokes was announced in his fundamental paper 'On the theories of internal friction of fluids in motion, and of the equilibrium and motion of elastic solids,' *Transactions of the Cambridge Philosophical Society*, Vol. VIII. † Cited above.

the motion of solids in such media, have been successfully worked out to results which agree fairly well with experiment. But on the whole, notwithstanding the searching investigations in this field of Stokes, Maxwell, Helmholtz, Boussinesq, Meyer, Oberbeck, and many others, it must be said that difficulties, both in theory and in experiment, of a formidable character remain to be surmounted.*

Of all branches of hydromechanics there is none of so great practical utility and of such widely popular interest as the theory of tides and waves. These phenomena of the sea are appreciable to the most casual observer; and there has been no lack of impressive descriptions of their effects from the days of Curtius Rufus down to the present time. The mechanical theory of tides and waves is, however, a distinctly modern development whose perfection must be credited to the labors of the mathematicians of the present century.†

Here, again, progress is measured from the advanced position occupied by Laplace, who was the first to attempt a solution of the tidal problem on hydrokinetic principles. After the fundamental contributions of Laplace, contained in the second and fifth volumes of the 'Mécanique Céleste,' the next decisive advance was that made by Sir George Airy (1801–1892), in his article on tides and waves, which appeared in the Encyclopædia Metropolitana in 1842. A quarter of a century later came the renaissance, started undoubtedly by the great memoir of Helmholtz and by the Natural Philosophy of Kelvin and Tait, along with Lord Kelvin's inspiring communications on almost every phase of wave and tidal problems to scientific societies and journals. Then followed the decided theoretical improvements in tidal theory of Professor William Ferrel,* particularly in the development of the tide generating potential and in the determination of the effects of friction. And a little later there appeared the novel investigations of Professor G. H. Darwin, who, in addition to furnishing a complete practical treatment of terrestrial tides,† has extended tidal theory to the solar system and thrown an instructive light on the evolutionary processes whence the planets and their satellites have emerged and through which they are destined to pass in the future.‡

As we reflect on the progress which has been thus summarily, and quite inadequately outlined, it will appear that the mathematicians of the nineteenth century have contributed a splendid aggregate of permanent accessions to knowledge in the domain of the more exact of the physical sciences. And as we turn from the certain past to the less certain future, one is prone to conjecture whether this brilliant progress is to continue, and, if so, what part the

*An extremely interesting method of experimental investigation has been recently applied with success by Professor Hele-Shaw. See a paper by him on 'Stream-line motion of a viscous film,' and an accompanying paper by Sir G. G. Stokes on 'Mathematical proof of the identity of the stream-lines obtained by means of a viscous film with those of a perfect fluid moving in two dimensions.' Report of British Association for the Advancement of Science for 1898.

† An excellent summary of the history and theory of tides, and of methods of observing and predicting them, is given by Dr. Rollin A. Harris in his 'Manual of Tides,' published as Appendices 8 and 9 of the Report of the U. S. Coast and Geodetic Survey for 1897.

American Mathematical Society may play in promoting further advances. With respect to these enquiries I should be loath to hazard a prediction or to offer advice. But there appears to be no reason for entertaining other than optimistic expectations. The routes along which exploration may proceed are numerous and attractive. We have only to follow the example set by Laplace, Poisson, Green, Gauss, Maxwell, Kirchhoff, Saint-Venant, Helmholtz, and their eminent contemporaries and successors. In commending the works of these great masters to the younger members especially of the American Mathematical Society, I would not be understood as urging the cultivation of pure mathematics less, but rather as suggesting the pursuit of applied mathematics more. The same sort of fidelity to research and the same sort of genius for infinite industry which enabled those masters to accomplish the grand results of the nineteenth century, may be confidently expected to achieve equally grand results in the twentieth century.

COLUMBIA UNIVERSITY.

CRUISE OF THE ALBATROSS.

II.

THE following letter from Dr. Agassiz, dated Papeete Harbor, Tahiti Island, November 6, 1899, has been received by the United States Fish Commission and is here published by courtesy of Commissioner Bowers.

During our stay in Papeete some time was spent in examining that part of the barrier reef of Tahiti which had been surveyed by the *Challenger*. We found the condition of the outer slope of the reef quite different from its description as given in the *Challenger* narrative. The growing corals were comparatively few in number, and the outer slope showed nothing but a mass of dead corals and dead coral bowlders beyond 16 or 17 fathoms, few living corals being observed beyond 10 to 12 fathoms.

We also made an expedition to Point Venus, to determine, if possible, the rate of growth of the corals on Dolphin Bank from the marks which had been placed on Point Venus by Wilkes, in 1839, and by MM. Le Clerk and de Bénazé, of the French navy, in 1869. We found the stones and marks as described, but, in view of the nature and condition of Dolphin Bank, did not think it worth while to make a careful survey, as Captain Moser had intended to do. On examining Dolphin Bank in the steam launch I was greatly surprised to find that there were but few corals growing on it. I could see nothing but sparsely scattered heads, none larger than my fist, the top of the bank being entirely covered by nullipores. We sounded across the bank in all possible directions and examined it thoroughly, and at the stage of water at which we sounded, found about 18 inches difference from the soundings indicated by the charts. It is also greatly to be regretted that Dolphin Bank was not examined, neither in 1839 nor in 1869, and notes made of what species of corals, if any, were growing on its surface; for an excellent opportunity has been lost to determine the growth of corals during a period of 60 years. The choice of this bank as a standard to determine the growth of corals was unfortunate, as it is in the midst of an area comparatively free from corals.

Extensive collections have been made at Papeete during our visit by the naturalists of the *Albatross*.

After refitting and coaling here, we left on the 5th of October for a cruise in the Paumotus.

We steamed for Makatea, which we had visited on our way to Tahiti, and not only examined the island more in detail, but took a number of photographs of the cliffs on the east side, which, on our first trip, we passed late in the afternoon. We crossed the island from west to east, the path leading down from the summit of the cliffs bordering the island into a sink at least 40 to 50 feet lower than the rim of either face of the island. The sink occupies a little more than one-third the length of the island. It is deeper at its southern extremity, where it is said to be 75 to 100 feet below the rim of the adjoining cliffs.

It is difficult to determine if this sink is the remnant of the former lagoon of the island, or of a sound formed during its elevation; or if it has been formed by the action of rain and atmospheric agencies. The amount of denudation and erosion to which this island has been subjected is very great, as is clearly indicated by the small cañons, pinnacles, and walls of limestone, as well as by the crevasses which occur in the surface of the basin in all directions. The extent to which this action has penetrated into the mass of the island is also plainly shown by the great number of caverns which crop out at all levels along the sea face of the cliffs, some of which are of great height, and extend as long galleries into the interior of the island. It is, of course, difficult, in the face of this extensive denudation and erosion, to state positively what may be part of the ancient lagoon, or sound, and what has been carried away by atmospheric and other agencies since the elevation of the island. At the south end of the island, which is lower than the northern part, there are only two distinct terraces, while at the northern end four terraces can be traced. The southern extremity, however, is still higher than the deepest part of the central sink of the island.

From Makatea, we visited Niau, Apataki, Tikei, Fakarava, Anaa, Tahanea, Raroia, Takume, Makemo, Tekokota, Hikueru, Marokau, Hao, Aki-Aki, Nukutavake, going as far east as Pinaki, when we turned westward again to Nukutipipi.

On arriving at Pinaki we decided to give up the exploration of the eastern extremity of the Paumotus, and not to make our contemplated visit to the Gambier Islands, our time having been greatly curtailed by delays at Fakarava and Makemo, from bad weather and the non-arrival of our coal supply. We therefore reluctantly turned westward again and made for the Gloucester Islands. These, as well as Hereheretue, proved most interesting; they formed, as it were, an epitome of what we had seen on a gigantic scale in the larger atolls of the western and central Paumotus. We could see at a glance in such small atolls as Nukutipipi and Anu-Anurunga, the connection between structural features which, in an atoll 40 miles in length and from 10 to 15 miles in width, it was often difficult to determine.

Except at Nukutavake we found no village in which the habits of the natives had not been more or less modified by civilization. The Paumotu Islanders have practically given up building their own houses; they use European models and their roofs are composed in great part of galvanized iron. There are also but few of the original native canoes to be seen. In a few years all traces of their customs and crafts will have disappeared.

We also steamed by Kauehi, Tænga and Tuanaka. We anchored in Fakarava and Makemo lagoons, spending a number of days in both these atolls. We usually timed our visits to the islands where we could not anchor so as to spend the day, or the greater part of the day, at these atolls, making our passages at night, and sounding whenever practicable on the way.

After leaving Tahiti we made over 100 soundings. These have shown in a general way that the western islands are probably all on a great plateau connected perhaps by the 800-fathom line; that such islands as Anaa are probably on spurs or independent smaller plateau, separated from the main plateau by somewhat deeper water. The same may be the condition of Raroia and Takume and of Hao and Amanu, while such smaller and isolated peaks as Tikei, Aki-Aki, Nukutavake, and Pinaki, as well as the Gloucester Islands, rise from greater depths and are isolated peaks. At any rate, these soundings indicate, as do the soundings off the Fijis, that atolls do not necessarily rise from very great depths, and that in this characteristic atoll district, atolls are found, it is true, with steep slopes, but rising from moderate depths. The slopes of these atolls would probably resemble in every respect the slope of the elevated coralliferous limestone islands characteristic of the Lau Group in Fiji.

The deepest sounding among the Paumotus was on the line to the northward of Hereheretue in the direction of Mahetia, where we found a depth of 2524 fathoms, and a continuation of the red clay characterizing the soundings since we left Pinaki. In nearly all the soundings among the Paumotus, even at moderate depths not far from the atolls, we brought up manganese particles or small manganese nodules. The last haul, made in deep water on the way from Hereheretue, in 2440 fathoms, brought up at least half a ton of manganese nodules, the bottom being red clay.

We have now steamed about 2500 miles among the Paumotus, and although we had not the advantage of the accurate surveys of the English hydrographic charts, which made the exploration of Fiji so easy, yet from the structure of these atolls it was a comparatively simple task, by steaming around the islands and landing wherever practicable, to get a fairly good idea of their structure. We have seen nothing in this more extended examination of the group tending to show that there has anywhere been subsidence. On the contrary, the condition of the islands of the Paumotus cannot, it seems to me, be explained on any other theory except that they have been formed in an area of elevation; an area of elevation extending from Matahiva on the west to Pinaki in the east, and from the Gloucester Islands on the south to Tikei in the north, although the islands in the line of Mangareva to Tahiti are separated from the other Paumotus by a deep channel, nearly 200 miles wide and more than 2400 fathoms in depth, with scattered islets and atolls extending from Mangareva to Pinaki, and northward to Serle Island and beyond, islands which are not connected with the extensive plateau upon which the greater number of the Paumotu Islands to the westward of Hao rise.

All the islands we have examined are, without exception, formed of tertiary coralliferous limestone which has been elevated to a greater or less extent above the level of the sea, and then planed down by atmospheric agencies and submarine erosion, the greatest elevation being at Makatea (about 230 feet), and at Niau, where the tertiary coralliferous limestone does not rise to a greater height than 20 feet. At Rairoa it was 15 to 16 feet high. At other islands it could be traced only as forming the shore platform, from 50 to 150 feet wide, which forms the outer face of the Paumotus, and is so characteristic a feature of the atolls of the group. In other parts the old ledge could be traced cropping up in the interior of the outer rim, or in the open cuts connecting the lagoon with the outer sea face of the atolls. Everywhere the space between the outcropping of the old ledge, as I will call the tertiary coralliferous limestone, was filled with beach rock, or a pudding stone, or with a breccia or conglomerate of coralliferous material consisting in part of fragments of the old ledge and of fragments of recent corals and shells cemented together.

The appearance of the old ledge and of the modern reef rock is so strikingly different that it is very simple to distinguish the two, even when only comparatively small fragments are found.

We did not find in the Paumotus, as in Fiji, all possible stages of denudation and of submarine erosion between islands like Vatu Vara, Niau, Kambara, Fulanga, Ongea, Oneata, Ngele Levu, and Weilangilala, and atolls with a mere ring or surf to indicate their existence.

In the Paumotus the islands have been elevated to a very moderate height and probably to nearly the same height, for the old ledge forming the base of the modern structure is found exposed nearly everywhere at about low-water when it cannot be traced at a slightly greater elevation. This would readily account for the nearly uniform height of the islands throughout the group.

But there is another element which comes into play in this group, and has an important part in shaping the ultimate condition of these atolls. At the Fijis we have seen the submarine erosion continue until there is little left of many of the atolls beyond the merest small islet or rock to indicate its structure. In the Paumotus, in the great atolls which are evidently only the exposed summits of parts of ridges or spurs of an extensive tertiary coralliferous limestone bed, the rim of the atoll is, after having been denuded to the level of the sea, again built up from the material of its two faces which is thrown up on the wide reef flats both from the sea face and from the lagoon side. We do not find in the Fijis such huge reef shelves to supply such masses of material from the breaking up of the outer and inner edges of the tertiary limestone platforms, in addition to the fragments of recent corals growing upon the flat and its edges, which, when dead, are thrown up and formed into shingle and sand to form a pudding stone, or a conglomerate, or breccia, with the fragments of the old ledge on the top of the reef flats.

This pudding stone, or beach rock, is found on all the reef flats of the islands of the group. It forms great bars, at right angles usually to the shore-line, and upon the sea-face of these bars is thrown up coral shingle, both old and recent, which builds up short reaches of beaches separated by wide flats through which the sea rushes at high water, or merely covers the flats at low tide; while on the lagoon side of the wide reef flats a similar process is going on, throwing up finer sand among the beach-rock bars and along their sides, and thus building up, little by little, at first small sand bars, then larger bars, or islets, at right angles to the shore-line, and as they become larger by accretions from both sides, they finally form an island from 1000 to 1200 feet long, according to the width of the reef flat, extending from the lagoon edge of the flat to the sea face of the atoll. The sand bars, little by little, become covered with vegetation, and at some stages of tide appear like islands and islets situated a considerable distance within the lagoon. Whenever the material supplied both from the lagoon side and from the sea face is very abundant, the land ring becomes more or less solid, the islets become consolidated into islands, separated by narrow or wider cuts, until finally they form the larger islands which seem at first glance to form continuous land along the rim of the lagoon, but which are often seen to be separated according to local conditions by narrow cuts, which finally allow no water to pass through and merely indicate the former separation of the various parts of the land.

In the lagoons of atolls of such great length as some of these of the Paumotus, like Rairoa, Fakarava, Makemo and Hao, which are between 30 and 40 miles long, and others of less dimensions, considerable sea rises under the prevailing trades. The sea and wind generally follow the trend of the shores, both in the lagoon and along the sea face, so that the bars of beach rock act like buttresses and collect material at their inner and outer extremities, forming the sand bars and islets which eventually become the land rim of the lagoon. When the material is not from local causes very abundant, or is washed out over the flats, there are fewer islands, and often these are but mere islets or bars for long reaches of the shore, forming the characteristic weather faces of many of the lagoons.

Many of the lagoons are filled with shoals or ledges awash or a few feet above the sea-level. These shoals are parts of the old ledge which have not as yet been eroded, and the disintegration of which has gone far to supply material for the land of the outer rims of the atolls. In Fakarava there were no less than 36 islands and islets and ledges, parts of a former great flat, now broken up, existing parallel to the outer reef flat about four miles in the lagoon. Similar reef flats exist in Tahanea, where they form a secondary lagoon with two to three fathoms of water, extending nearly the whole length of the western face of the atoll. There are several large islands on this flat, and at high water they would appear as the islands and islets of Fakarava do, as disconnected and planted in the lagoon itself. A secondary lagoon also exists in Ravahere and Anaa; in both these atolls the reef flat extends across one extremity of the lagoon and does not run parallel to the longer shore-line of the atoll.

The lagoons of these atolls have a general depth of 13 to 20 fathoms. In some cases they are, as is stated, somewhat deeper (but there are no measurements), the greater depths being 30 fathoms or more, being due to orogenic conditions. Some of the atolls are quite shallow, as at Matahiva as well as Pinaki, where the lagoon is not more than two to three fathoms, and Takume, where it is from five to six fathoms deep. Some of the smaller islets we visited, among which are Tekei, Aki-Aki and Nukutavake, have no lagoons. The former has a shallow sink in which fresh water collects, but the rim is only very slightly higher than the interior. The last two islets are apparently depressed in the center, three to four feet below the outer bank of sand which forms the rim (about 10 to 12 feet high) of the basin of the island. I was at first inclined to look upon these islands as examples of islands which had been cut down to the level of the sea and subsequently been built up by beach rock and sand in the manner described above. The existence of extensive sand dunes on two sides of the island at Pinaki, and of a large dune (estimated to be 35 feet high) on the south shore of Nukutavake, seems to indicate the possibility of there having been a shallow lagoon occupying the center of Aki-Aki and of Nukutavake, and that these lagoons were gradually filled by the sand dunes, much as Pinaki is filling now.

At Pinaki (Whitsunday Island), there is no doubt but that the lagoon is rapidly filling from the sand blown in by the dunes. They are from 12 to 15 feet high and are forcing their way in towards the lagoon, killing the pandanus and whatever vegetation there is growing on the land rim of the lagoon. The dunes have probably filled also a second entrance to the lagoon, indicated now only by a somewhat lower level of the land rim. Mr. Moore and Mr. Townsend, who went ashore at Pinaki, report that the lagoon is not more than three fathoms deep; they could wade over the greater part of it. Mr. Alexander counted no less than 116 islets in this small lagoon —less than a mile in diameter—islets formed of masses of dead Tridacna shells thrown up on ledge rock, on the slopes of which grew madrepores. The bottom of the lagoon is covered by Tridacna and masses of a species of Arca live near the edge, the intervening spaces being filled with nullipores. The entrance to the lagoon is perhaps 150 feet wide, and there is a cut through the beach rock covering the old ledge, giving access to the sea into the lagoon at certain stages of the tide. The water in the lagoon is quite warm.

At Pinaki, as at other atolls and islets to the eastward, there are fewer cocoanuts than on the westward atolls, and the vegetation consists in great part of pandanus and puteau trees and the usual coral reef vegetation of the Paumotus and Fijis.

The only atoll we have seen, the lagoon of which is entirely shut off from the sea, is Niau. In this case the old ledge forming the rim of the land, which surrounds the nearly circular lagoon, is about a third of a mile in width, and sufficiently high, 15 to 20 feet, to prevent any sea from having access to it except in case of a cyclone, as that of 1878, when the sea washed into the lagoon. The lagoon is shallow, of an average depth of about three fathoms, the deeper parts perhaps five. The water is brackish, of a density of 1.0216 at 28 degrees C. There are no corals living in it, but a species of mullet is found, as well as many marine shells, which, like those in the lagoons of San Salvador, in the Bahamas, are of diminutive size compared to their representatives living outside. The floor of the lagoon is covered with algæ. The lagoon has probably a slight connection with the sea, the water percolating through the limestone ring separating it from the outer reef flat. It is very difficult in this case to decide whether this lagoon has been gradually filled up after elevation or whether it is merely a sink on a more or less uneven limestone surface.

Dana and the other writers on coral reefs mention a great number of lagoons as being absolutely shut off from the sea. I take it these statements are due to their descriptions being taken from charts, many of which (as in the case of the Paumotus) are very defective. For nothing is easier than to pass at a short distance by the wide and narrow cuts which give in so many places the freest access to the sea to the interior of the lagoons, and described as closed because they have no boat passages. I could mention as instances of such lagoons those of the atolls of Takume, Hikueru, Anaa, etc., which may be said to be closed, yet into which a huge volume of water is poured at every tide over low parts of the encircling reef flats.

The character of the coral reefs of the Paumotus is very different from that of other coral reef regions I have seen. Nowhere have I seen such a small number of genera, so many small species, and such stunted development of the corals. None of the great heads of the genera so characteristic of the West Indian regions, or of the great barrier reef of Australia, are to be seen; with the exception of a couple of species of alcyonaria they are absent, so far as our experience shows, and there are but few sponges and gorgonians to be found among the corals. The bathymetrical limit of the reef-building corals seems to be about 20 to 22 fathoms, but nowhere have I seen such extraordinary development of incrusting nullipores as on the sea edge of the shore platforms of some of the Paumotu atolls, where they build up to a height often four feet to form the outer edge of the secondary barrier reef so frequently seen along the reef faces of the Paumotus.

On the 4th of November we were well on our way to Mehitia, the easternmost of the Society Islands, the account of which will be included in my next letter giving the results of our examination of the Society Islands.

We have taken a large number of photographs to illustrate the structure and mode of formation of the Paumotu atolls. Mr. Mayer has devoted much time to the drawing of the medusæ collected.

Judging from the temperature taken at various points, 40° F. seems to be found quite generally at about 500 fathoms depth.

We made a number of surface hauls, as well as intermediate hauls, with the townets, but obtained very little animal life. The poverty of the surface pelagic life, and down to 300 fathoms, is remarkable. I do not think I have ever sailed over so extensive an area as that of the Paumotus and observed so little surface life; on calm days, under the most favorable conditions, nothing could be seen with the naked eye, and at night there was little or no phosphorescence. Inside the lagoons our hauls were equally barren.

The same paucity of animal life seemed to extend to the deep-water fauna. All the hauls we made off the islands, in from 600 to 1000 fathoms, usually the most productive area of a sea slope, brought nothing, or so little that we came to grudge the time spent in trawling on the bottom, as well as towing on the surface or near it, a great contrast to the conditions of the Atlantic in similar latitudes, and very different from our anticipations. For these reasons no attempt has thus far been made to make a trial of the deep-sea pump while in such unproductive areas, and unfortunately while we were in the region of the equatorial current the weather conditions were not suited for a trial of the apparatus.

We expect now to coal and refit, and to leave for Suva via Tonga on the 15th of this month. A. Agassiz.

THE TWELFTH ANNUAL MEETING OF THE GEOLOGICAL SOCIETY OF AMERICA.

I.

The Geological Society of America convened at 10 a. m., Wednesday, December 27th, in the large lecture room of Columbia University, Washington, D. C. President B. K. Emerson called the meeting to order and Dr. G. K. Gilbert delivered an address of welcome, to which the President responded. The following officers were then declared elected for the ensuing year:

President: George M. Dawson, Ottawa, Ont.; *First Vice-President:* Charles D. Walcott, Washington, D. C.; *Second Vice-President:* N. H. Winchell, Minneapolis, Minn.; *Secretary:* H. L. Fairchild, Rochester, N. Y.; *Treasurer:* I. C. White, Morgantown, W. Va.; *Editor:* J. Stanley-Brown, Washington, D. C.; *Librarian:* H. P. Cushing, Cleveland, O.; *Councillors:* W. B. Clark, Baltimore, Md., and A. C. Lawson, Berkeley, Calif.

The following new Fellows were also announced as having received election:

Irving Prescott Bishop, 109 Norwood Avenue, Buffalo, N. Y., Professor of Natural Science, State Normal and Training School; Emilo Böse, Ph.D. (University of Munich, 1893), Calle del Paseo Nuevo No. 2, Mexico, D. F., Geologist of the Instituto Geologico de Mexico; Arthur Starr Eakle, B.S. (Cornell, 1892), Ph.D. (Munich, 1896), University Museum, Cambridge, Mass., Instructor in Mineralogy and Petrography, Harvard University; August Frederick Foerste, A.B. (Denison, 1887), A.M., Ph.D. (Harvard, 1888, 1890); John Flesher Newsom, A.B. (University, Indiana, 1891), A.M. (Stanford, 1892), Stanford University, Calif., Associate Professor of Metallurgy and Mining, Stanford University; Samuel Lewis Penfield, Ph.B., M.A. (Yale, 1877, 1896), New Haven, Conn., Professor of Mineralogy, Sheffield Scientific School of Yale University; Charles Henry Richardson, A.B., A.M., Ph.D. (Dartmouth, 1892, 1895, 1898), Hanover, N. H., Instructor in Chemistry and Mineralogy, Dartmouth College; Arthur Brown Willmott, B.A., B.Sc. (Victoria University, Toronto, 1887), M.A. (Harvard, 1891), Toronto, Canada, Professor of Geology and Chemistry, McMaster University.

During the year the Society has lost by death four of its most distinguished Fellows, of whom two, Sir J. William Dawson and Edward Orton, have been presidents. The others were O. C. Marsh and Oliver Marcy. Memorials were read of all but Professor Marsh, whose biographer, Professor C. E. Beecher, was absent, and had failed to send his manuscript. Extemporaneous remarks were made after the reading of each of the memorials, and they were often marked by deep feeling, as one after another of the former students of the departed scientists paid his tribute to his old teacher and friend. The first paper was then read as follows:

Physiographic terminology with special reference to land forms. By W. M. DAVIS, Cambridge, Mass.

The paper embraced a critical discussion and a definition of terms, mostly suggested within the last thirty years, for the description of land forms. The terms cycle, base-level and grade were considered in detail.

The general principle was advocated that terms should be based on observation and should express its results. The geographical cycle was urged as the basis. Instead of the old conceptions of destructional and constructional; initial, sequential and ultimate were suggested. It was urged that for 'base-level' as applied to the limiting conditions of the development of a river 'graded slope' be substituted—as base-level has now a variety of meanings. Other terms involving the syllables 'sequent,' such as consequent, obsequent, insequent, subsequent, etc., were suggested and defined. In discussion B. K. Emerson referred to the difficulty of remembering the distinctions in meaning among so many similar terms, a remark that struck a sympathetic chord in the minds of all teachers present.

Camas Land, a valley remnant. By GEO. OTIS SMITH and GEO. CARROLL CURTIS, Washington, D. C., and Boston, Mass.

A description was given of the remnant of an old valley on the eastern slope of the Cascade Mountains, in Washington (Mt. Stuart quadrangle). Camas Land owes its preservation above the circumdenudation to an intrusive sheet of diabase. A relief model of Camas Land was exhibited which made clear to all present the peculiar phenomena of the region and the rearrangement of the drainage. Discussion by W. M. Davis and M. R. Campbell ensued, which, however, would require the model to be intelligible to one not present.

Some coast migrations, Southern California. By BAILEY WILLIS, Washington, D. C.

The section of the California coast described extends from Point Sur to Piedras Blancas, between Monterey and San Luis Obispo. Formations constituting the Santa Lucia Range of the Coast Ranges were described, their relations to each other stated, and the corresponding migrations of the Pacific Coast were indicated with probability. A review of the observations of Fairbanks was presented.

It was shown that the oldest rocks constitute a series of metamorphic schists and that on these rest the Jurassic, Cretaceous, Miocene and Pliocene series. The schists are intruded by granite. Five thousand feet above the Pacific the Miocene beds are met dipping eastward and thinning out in that direction. This indicates a great land area which must have existed in the Miocene, where now is the Pacific ocean; 3000 feet above the sea, folded Pliocene strata occur. There are, therefore, two submergences indicated and great elevation and disturbances in comparatively recent geologic time.

Submerged forest of the Columbia River. By G. K. GILBERT, Washington, D. C.

At the Cascades the Columbia river flows over a natural dam of rock fragments. In the pond above stand sound stumps of Douglas spruce. Of various explanations proposed that first suggested by Lewis and Clark and repeated by Gibbs and Newberry accords best with the facts. The river was dammed by a land slide from the north not less than 350 years ago.

The speaker reviewed the explanations

of other observers and the Indian legends. He showed the general topography and geology by means of maps, and explained his estimate of the lapse of time by the rings in the stumps of trees which had grown on the landslide. There is also a river terrace about 100 feet above the present water level. The landslide therefore ponded the river and drowned the trees standing above it. In discussion J. A. Holmes cited cypress trees, in good preservation, 20 feet below the bottoms of rivers in North Carolina, and G. B. Shattuck spoke of similar cases in Maryland in the Pleistocene.

Physiographic development of the Washington region. By N. H. Darton, Washington, D. C.

A general sketch was presented, illustrated by maps and photographic illustrations, and intended to give visiting geologists an outline of the principal features of the Mesozoic to recent geology.

The paper was not meant for publication, but it served to set before the Society an excellent idea of the geological formations near Washington and their physiographic development.

Erosion forms in the Harney Peak District, Black Hills, South Dakota. By Edmund Otis Hovey, New York City.

The paper consisted of the exhibition of about ten lantern slides, showing the peculiar forms produced by erosion in the schists and pegmatites in the Harney Peak District in the Black Hills of South Dakota.

The slides illustrated the curiously sheeted and jointed granite which leads to the production of very rough topography. Pictures of the large spodumene crystals at the Harney Peak tin mines were also thrown upon the screen.

In discussion President Emerson compared the spodumenes with those of Massachusetts. S. F. Emmons described the occurrence of the spodumenes in pegmatites. I. C. Russell inquired if there were evidences of glaciation in the hills; Mr. Hovey replied, no. A. C. Spencer inquired if the Sylvan Lake was a rock-basin. This was likewise answered in the negative.

Topographic features of Ohio. By W. G. Tight, Granville, O.

The general topographic features of the different sections of the State were discussed and an attempt was made to show the reasons for the different types. The paper was illustrated with lantern views.

The author remarked the paucity of information about the physiography of the State in general. He divided it into three areas: the northwestern, within the limits of the glacial ice; the border, a belt along the terminal moraine; and the southeastern, outside the drift. The readjustments of drainage and the various topographic forms were admirably illustrated. In discussion M. R. Campbell inquired if there was good evidence of peneplains in the southeast; the author replied that there was some but that it was not conclusive. I. C. White discussed the general directions of the drainage.

Drainage modifications in Southeastern Ohio. By W. G. Tight, Granville, Ohio.

The changes in drainage of the region north of the Ohio river and between the lower Muskingum and the lower Scioto have been very great. The lower Muskingum, south of Zanesville, is shown to be a composite stream made up of sections of four preglacial streams which crossed the course of the present Muskingum. These four streams united in what is now the Little Hocking basin, and the main line of preglacial drainage extended across the present Hocking river, which is also shown to be composed of sections of several preglacial streams, into the basin of Raccoon creek and across this basin into that of the Scioto river below Chillicothe. Several of the tributaries of this preglacial river were also described.

The paper gave a very graphic conception of the rearrangements which were brought about by the continental ice sheet, changing the outlet of the river system from the Great Lakes to the Mississippi. In discussion M. R. Campbell brought up the Teazes valley and the changes in the Big Kanawha, and the presence of silt in the former. W. G. Tight then described the area covered by silt and referred the readjustment of the drainage to the obstruction which it presented. The silting was explained by some barrier far to the westward. I. C. White referred to his early description of the valley, and urged the danger of mistaking, for cols, narrows in the Ohio and other rivers produced by the crossing of some hard stratum. The author replied that he had sought to guard against this.

The landslides of the Rico Mountains, Colorado. By WHITMAN CROSS, Washington, D. C.

The Rico Mountains, in southwestern Colorado, are due to the erosion of a local domatic uplift. The sedimentary formations affected embrace the Algonkian, Devonian, Carboniferous, Permo-Carboniferous, Juratrias and Cretaceous. Many intrusive dikes, sheets and small laccoliths of diorite—or monzonite—porphyry occur in this complex. A large monzonite stock penetrates all rocks above mentioned. Intense and complicated faulting has taken place in the heart of the uplift, and there has been a great amount of mineralization, forming argentiferous ore bodies of many types.

Landslides, occurring in a recent geological epoch, are very prominent features of the local geology. These landslide areas were described, the relation of the phenomena to other elements of the geological history were discussed, and hypotheses of their origin set forth.

The landslides are limited to the central portion of the domatic uplift. No apparent connection can be traced between the structure and the slides, nor are they present in the region of greatest faulting. The speaker finally concluded that they were connected with deep, interior vulcanism, transmitted through the intruded stock of monzonite.

J. B. Woodworth mentioned similar cases in southwestern Montana, where water-bearing beds caused the slipping. W. M. Davis mentioned Alpine cases where glacial erosion had removed the support. Dr. Cross said there was no glaciation at Rico. W. H. Niles also referred to Alpine cases. Geo. Otis Smith mentioned similar cases in the Stewart mountains, Oregon, where, of all the rocks present, the granite is alone unaffected.

A recent fault scarp in the Lepini Mountains, Italy. By W. M. DAVIS, Cambridge, Mass.

The Lepini mountain group is a submaturely dissected block of cretaceous strata, 40 miles S. E. of Rome. Recent movement on the line of a tertiary fault has produced a well-defined scarp in places 100–200 feet in height and traceable five miles or more along the northeastern base.

The paper was finely illustrated by the lantern and the truncations of fan-like projections of rock called rock-fans were well shown. There was no discussion. The reading of the paper closed the first day's proceedings.

On Wednesday evening the President, Professor B. K. Emerson, delivered his presidential address upon 'The Tetrahedral Earth and the Zone of the Intercontinental Seas,' before a large gathering of the Society and their friends. It will appear in another number of SCIENCE.

The Society convened in business session Thursday morning at 9.30 o'clock. The report of the Council was submitted and approved. Reports were received from the photographic committee which shows that a collection of over 1900 views has been made. The committee then resigned and N. H. Darton was elected a committee of one to have charge of the matter. A motion was passed approving of the organization of a Cordilleran Section to embrace the members living on the Pacific coast, who by reason of distance cannot meet with the Society, and a telegram of greeting was sent to them in their first session.

The report of the Council showed the Society to be in a very prosperous condition. There are 239 Fellows, besides the 8 elected at this meeting. The Society has an invested fund of $5,000, and on account of an unavoidable delay in issuing Vol. X, had also a balance, December 1st, of $3,030.02. The Society is, however, very anxious and ambitious to increase its invested funds in order that the income may admit of the suitable illustration of papers.

Deposits of calcareous marl in Michigan. By Israel C. Russell, Ann Arbor, Mich.

A large number of lakes and swamps in the southern Peninsula of Michigan have been found to contain deposits of calcareous marl suitable for the manufacture of Portland cement. The marl is composed in part of shells, but is mainly a chemical precipitate and is still being deposited. The better grades contain from 80 to 95 per cent. of calcium carbonate. Several large cement works have already been established and others are contemplated. The supply of marls is practically inexhaustible and Michigan can easily take a leading place in the Portland cement industry.

The precipitation of the calcareous matter is probably due to the fact that calcium carbonate is more soluble in cold water than in warm, and as the lakes are fed by springs, the waters rise in temperature and lose their dissolved material.

J. F. Kemp referred to the importance of the industry and the previous efforts that had been made near Syracuse to utilize the same materials. J. M. Clarke emphasized the possible part played by algæ in precipitating the calcium carbonate. The speaker replied that he had not found much evidence of them.

Glacial origin of the older Pleistocene in the Gay Head Cliffs, with a note on the fossil horse of that section. By J. B. Woodworth, Cambridge, Mass.

The occurrence of glaciated fragments in the boulder bed at the base of the older Pleistocene (Columbia) in the Gay Head Section was described and illustrated, confirming, it is thought, the theory of the existence of an ice invasion long antedating the surface moraines of the New England islands. The astragalus of a mammal identified with that of a horse, by Professor Osborn, was exhibited. This bone was found in the Miocene underlying the boulder bed at Gay Head.

Beach structure in Medina sandstone. By H. L. Fairchild, Rochester, N. Y.

The papers involved an exhibition, by lantern slides, of structural features in the Medina which indicate shallow water and beach deposits. The speaker referred to the phenomena described by G. K. Gilbert at a previous meeting as giant ripples, which suggested waves of 60 ft. height. Many views were shown illustrating them, and small ripple marks were seen on these crests. Individual cases without parallel neighbors were exhibited. The phenomena were then interpreted by the action of actual waves on the beach of Lake Ontario and they were explained as due to shore-wave action. C. W. Hayes cited similar phenomena on the San Juan River, Nicaragua, and H. S. Williams described channel fillings in the Devonian beds near Ithaca, which threw light on the cases in point.

Glacial erosion in the Aar Valley. By ALBERT PERRY BRIGHAM, Hamilton, N. Y.

Observations were made between Meiringen and the Abschwung. The valley has several relatively broad and open sections, containing small rock basins. These basins are filled with alluvial material. One double basin, however, that of the Grimsel Lakes, being out of the track of the stream, keeps its water-filling. Between the basins, in some cases, are narrow V-shaped gorges, bordered by heavily glaciated spurs thrown out from the valley sides. The sides of the gorges are often glaciated nearly to the bottom. In other cases rock barriers have crossed the valley and are now breached by very narrow post-glacial gorges, as above the Grimsel Hospice and above Meiringen. Supplementary illustrations were given from the Rhone and Visp Valleys.

W. M. Davis in discussion illustrated the discordance between side valleys and the main valley—the former discharging at an altitude of some hundreds of feet above the floor of the latter. These discordant, lateral valleys were called 'hanging valleys.' I. C. Russell remarked the same phenomena in the Sierras and Cascades. Bailey Willis emphasized the excess of lateral erosion by glaciers over the vertical and that thus the natural grade of the side valleys had been truncated. W. H. Niles laid stress on the importance of subglacial streams, along the sides of a glacier. G. K. Gilbert urged the efficiency of glacial erosion and stated that the profiles of lateral valleys did not coincide with the idea of truncation. The discordance may be met in rivers, as along the Rio Virgin, where the main stream deepens faster than the laterals. J. J. Stevenson corroborated the same views by the valley of the Twin Lakes in Colorado. J. W. Spenser described the hanging valleys of Norway, which are step-shaped at the discordance. I. C. White described discordance along the Monongahela Valley, where no glacier had ever existed. S. F. Emmons cited hanging valleys along the Columbia River, where it crosses the national boundary. H. W. Turner mentioned cases in the Sierras in the Bidwell Bar quadrangle. A. P. Brigham confirmed the power of a glacier to erode. W. M. Davis closed the discussion.

Movement of glaciers. By HARRY FIELDING REID, Baltimore, Md.

The paper gave the results of from one to three years' observations on the movement of the Forno glacier, with special reference to the vertical component of the movement. The existence of surfaces of finite shear in glaciers was discussed. The author described the set of stakes that he had set up at several places across the glacier and had watched for two or three years. They showed a slow movement at the end and a more rapid one up the ice-stream, and some interesting relations at the névé. He proceeded at once to the reading of his second paper.

Stratification and banded structure of glaciers. By HARRY FIELDING REID, Baltimore, Md.

Careful work on a number of the Swiss glaciers has enabled the author to follow the outcrops of the strata from the névé-line practically to the end of the glacier, and has convinced him that the banded structure is the modified appearance of the outcrops. A reason is suggested why glacialists have held divergent views on this subject. With a beautiful and complete series of lantern slides the author illustrated the evidences of stratification and the phenomena of movement. He distinguished stratification lines from the banding due to pinched crevasses and to other causes, and discussed the differences of Agassiz and Forbes regarding these phenomena. Bailey Willis commented on the close parallelism between ice movement and rock movement and inquired regarding the phenomena of movement. Dr. Reid replied that there was no shearing at all, but that plasticity sufficed to explain all the observed phenomena.

A channeled drumlin. By H. L. FAIRCHILD, Rochester, N. Y.

A few lantern views showed a longitudinal hollow (channel?) in a drumlin terminating at the lower end by a transverse cut.

The phenomena had puzzled the writer and after illustrating them he appealed to the Society in vain for an explanation.

Distinction between Upper and Lower Huronian. By A. P. COLEMAN, Toronto, Canada.

During the past summer a band of rock consisting of fine-grained sandstone, chert or jasper, with interbedded iron ore, has been found at Michipicoton, on the northeast shore of Lake Superior, corresponding to the Vermilion and other iron-bearing series west and south of Lake Superior. This band has been traced for 30 or 40 miles, and has been recognized at various points to the west as far as Rainy Lake and east to Lake Temagami. It is the most easily determined member of the Lower Huronian. Many fragments of this sandy, cherty or jaspery rock are found, as well-rounded pebbles in conglomerates of the Upper Huronian, at Gros Cap, a few miles west of Michipicoton, and at other points as far west as Shoal Lake and east as Lake Temiscaming, a distance of more than 600 miles. Jasper and other pebbles of these rocks furnish an easily applied test of the Upper Huronian, since their materials can have come only from the Lower Huronian. The basal conglomerates near Thessalon and also on Lake Temiscaming contain jasper pebbles, and hence indicate only the base of the Upper Huronian. This far-reaching break between the two parts of the series represents a great lapse of time, as proved by the Shoal Lake conglomerate.

In discussion C. D. Walcott disclaimed any conflict in the meaning of Algonkian and Huronian, making the former a much wider and more inclusive term than the latter.

The Cambrian formation in the Atlantic province. By CHARLES D. WALCOTT, Washington, D. C.

The work of Dr. G. F. Matthew and the use of the term Etcheminian series, by him, for a sedimentary series formerly considered to be pre-Cambrian and to be separated by a break from the Cambrian, was reviewed. The presence of a stratigraphic break between the Etchenimian and Cambrian was found not to exist. The apparent break is explicable by folds. The same relations were found in Newfoundland. Views were shown illustrating the Smith's Bay and Manuel's Brook localities.

The Lower Devonian aspect of the Lower Heidelberg and Oriskany formations. By CHARLES SCHUCHERT, Washington, D. C.

The Silurian of Murchison was compared with the American equivalents. The Devonian of Sedgwick and Murchison has no marked Lower Devonic fauna. The Lower Devonic of Germany was summarized. The Helderberg fauna is transitional to the Oriskany, and these two constitute the American Lower Devonic.

The paper was read by J. M. Clarke and the next three titles were taken up before discussion was begun.

The Silurian-Devonian boundary in North America. By HENRY S. WILLIAMS, New Haven, Conn.

The writer presented a discussion (*a*) of the principles to be used in determining the boundary between the two systems, Silurian and Devonian, the standard sections of which are on another continent, and (*b*) of the facts of correlation bearing upon the case.

He urged that to establish the top of the Silurian as the word was used by Murchison, we must find the equivalent of the Tilestone fauna. This has been done in the Arisaig fauna of the Maritime provinces, which is well developed in northern Maine and which lies over the Helderberg fauna at the same place. He therefore developed an argument for retaining the Helderberg in the Silurian.

The contact of the Silurian and Devonian in Erie Co., N. Y. By A. W. GRABAU, Troy, N. Y.

A limestone known as the Bullhead rock was found to contain fossils like those described by Whitfield from the Helderberg of Ohio. There is an unconformity between the Bullhead rock and the overlying Onondaga. A sandstone dike in a crevice in the limestone was described and some suggestions regarding the choice of a name for the Bullhead rock were made. The Manlius limestone was finally adopted, it having been used by Dr. J. M. Clarke.

Devonian strata in Colorado. By ARTHUR C. SPENCER, Washington, D. C.

The presence of Devonian rocks in southwestern Colorado, asserted by F. M. Endlich in 1874, has been confirmed by observation of the United States Geological Survey party under the direction of Dr. Whitman Cross.

The section when complete is threefold, consisting of a conglomerate and sandstone at the base, followed by a calcareous shale, and this by a massive limestone containing considerable numbers of invertebrate fossils. The limestone is shown by its outcrops to have covered an area of at least 600 square miles. The sandstone and shale beds are locally absent through non-deposition. Their age is possibly Silurian, though they contain occasional fish remains, which would ordinarily be considered indicative of the Devonian. The silicious series is correlated with the 'Parting Quartzite' of central Colorado, and mention is made of further probable equivalency between this series and the supposed Devonian of the Grand Canyon region. This brings out the probability that these formations of the Middle Paleozoic were originally deposited over a very extensive area in the southern Rocky Mountain region.

The fossils have been studied by Dr. George H. Girty, who considers that they are representative of a fauna older than that of the Chemung, and probably belonging at the base of the upper Devonian or near the top of the lower. Collections made by various geologists in central Colorado, are found to contain the same assemblage of fossils and to afford a basis for correlation. The fauna resembles that described by Whiteaves, from Hay River, Canada.

All four Devonian papers were discussed together. J. M. Clarke urged, regarding the delimitation of the Silurian, that it should rest upon the organic forms and their culmination, and not on the classification of Murchison. He then emphasized the Devonian aspects of the Helderberg of New York most strongly, and stated that its rich fauna should decide the question and with it the Arisaig would go. Dr. Clarke also corroborated the observations of Grabau by his own studies in the cement quarries of Buffalo.

H. S. Williams stated his method of solving the Devonian question as an endeavor to find in America an equivalent section to the classic section of the Old World. He therefore had searched for it in Maine and had discovered one above the Helderberg, which was almost exactly equivalent to the Tilestone. Other contrasts were instanced. C. H. Hitchcock remarked the importance of northern Maine as a place to decide this question, and mentioned Lake Telos as a promising locality. H. S. Williams again spoke, bringing up the Gaspé section and mentioning facts about northern Maine. J. M. Clarke also remarked his acquaintance with the Devonian fossils from Maine and reaffirmed the finality of the organic tests of correlation.

These papers concluded the session of Thursday. In the evening at 7.30 o'clock the Society assembled at the Hotel Raleigh for the annual banquet. To the delight of all present, Professor Emerson was found at the head of the table, and as usual a very merry evening followed. According to the admirable custom, now well established, the fellows brought their wives, and the ladies gave a brilliant aspect to the dinner. Ninety-five covers were laid, including about 15 for ladies.

J. F. KEMP.

COLUMBIA UNIVERSITY.

SCIENTIFIC BOOKS.

Frontinus and the Water Supply of the City of Rome. By CLEMENS HERSCHEL, Hydraulic Engineer. Boston, Dana Estes & Co. 1899. 4to. xlix + 296 pages.

Frontinus was appointed water commissioner of Rome in 97 A.D., and soon thereafter wrote his two books, generally called De Aquis, on its waterworks. The sole original Latin manuscript, dating from the twelfth or thirteenth century, is preserved in the library of a Benedictine monastery in Italy, and the photographic reproductions of its twenty-four pages which Mr. Herschel gives will be of interest to classical scholars. He also gives the Latin text and its English translation on facing pages, and adds twelve chapters of explanatory and critical matter which are of special value to civil engineers and archæologists; these are accompanied by eighty-four illustrations and three folding plates. This is the first time that De Aquis has appeared in English translation, and it is safe to say that no single volume has ever been published that contains such a wealth of information on the water supply of ancient Rome.

The treatise of Frontinus begins with a description of the nine aqueducts erected prior to 97 A.D., mentioning their builders, sources and lengths. The subject of water measurement is next discussed and the sizes of the standard pipes are given, this being preparatory to determining the amount of water furnished by each aqueduct and how much was used for fountains, for public buildings and for private uses. Then the quality of the waters and the laws for the prevention of pollution receive attention, and this is followed by a statement of the duties and powers of the water commissioners, and of the regulations for preventing the unlawful use of water. Lastly, the methods of repairing the aqueducts are discussed, and the laws for ensuring their proper maintenance are given.

Mr. Herschel discusses at length the engineering and hydraulic features of the aqueducts and of the methods of distributing the water. It is clearly shown that the Roman engineers had no rational methods of measuring water, such quantities as cubic feet per second or gallons per hour being beyond their powers of conception. The unit of measurement used by them was called a 'quinaria,' this being originally a circular pipe whose diameter was $1\frac{1}{4}$ Roman digits, later the number of square units in the cross-section of this circle, and later the quantity of water passing through this area. Evidently it was understood that the discharge through a pipe or channel would vary with the velocity, as Frontinus says that the aqueduct Virgo could not be properly measured near its source, where the current was too slow, but near the city where the velocity was greater he found it to give 2504 quinarias. In general, however, the measurement of water was made by finding the area, in quinarias, of the cross-section of the channel or pipe; thus a denaria pipe, whose diameter was double that of the quinaria pipe, was supposed to discharge four quinarias of water.

The statement is commonly made in cyclopædias that the aqueducts of ancient Rome delivered about 300 gallons of water per day for each inhabitant, a consumption about three times as great as that of American cities. This statement is traced by Mr. Herschel to certain hypothetical computations published by Prony in 1817, which are shown to rest upon unwarranted assumptions. A probable value of the quinaria is found in three different ways: first, by computations from the measured cross-section of an aqueduct now standing and the ancient slope of its water surface as marked by the incrustations of the deposited limestone; second, by actual gaugings of those ancient aqueducts that are now in use; and third, by computations from reasonable data of the discharge of pipes which delivered water to houses. An analysis of the work of Blumenstihl and Belgrand leads to the conclusion that the value of the quinaria was somewhere between 2500 and 9000 gallons per day. Accepting the statement of Frontinus that 14,000 quinarias were delivered within the city, and calling its population one million, it follows that the consumption was between 35 and 126 gallons per person per day, and when it is considered that one or more of the aqueducts were generally out of service owing to the progress of repairs, the lower figure is probably nearer to the actual consumption. Mr. Herschel's final conclusion is that the probable daily consumption was 38 gallons per person, although the actual value doubtless varied some 20 gallons on either side of that figure.

The Roman laws regarding the injury of aqueducts, the pollution of their waters, and the unlawful use of water have formed the basis of modern statute law for the protection of public water supplies. Regarding the distribution of water to buildings, it is interesting to note that direct connections with the aqueducts and street mains were forbidden; these mains delivered the water to small distributing tanks, and a house connection was made to one of these tanks by a quinaria pipe. It was required by law that this pipe could not be increased in diameter within a distance of fifty feet from the tank, since by so doing the discharge would be increased. These water tanks were under the charge of men called 'aquarii,' who probably bought the water from the city and sold it to consumers, since various methods devised by them to defraud both the city and the consumers are described and severely denounced by Frontinus.

Roman arithmetic and mensuration form the subject of one of Mr. Herschel's interesting chapters, but his statement that Frontinus used for π the value $3\frac{1}{7}$ seems to be scarcely warranted. In fact the list of fractions used by Frontinus does not contain $\frac{1}{7}$, that list being $\frac{1}{2}$, $\frac{1}{3}$, $\frac{1}{4}$, $\frac{1}{6}$, $\frac{1}{12}$, $\frac{1}{24}$, $\frac{1}{36}$, $\frac{1}{48}$, $\frac{1}{72}$, $\frac{1}{288}$, and multiples of these. From the diameters and circumferences of several pipes, as stated in De Aquis, the writer concludes that the value of π used in computing the latter from the former was probably $3\frac{41}{288}$, or, in the notation of Frontinus, $3 + \frac{1}{12} + \frac{1}{24} + \frac{1}{72} + \frac{1}{288}$.

Mr. Herschel remarks that Frontinus takes high rank, even to-day, as a practical superintendent of waterworks. His first care on assuming the office was to ascertain the history of the aqueducts and the regulations and customs regarding the measurement of the water; then he made gaugings to ascertain the amount of water carried by the aqueducts and the consumption. Finding the latter far less than the former, he traced the discrepancy to unlawful connections. The laws relating to these were then enforced and measures taken to prevent waste. The result was that "the cleanliness of the city is greatly improved, the air is purer, and the causes of pestilence are removed"; at the same time "those who with fear drew water unlawfully, draw their supply now free from care, by grant from the sovereign," and thus morality was promoted.

It is a matter of congratulation that the first English translation of Frontinus' De Aquis should have been made by a hydraulic engineer highly qualified to interpret it. In fact our knowledge of Frontinus and his work is mostly due, not to classical scholars, but to technical men, the French and German translations having been made by the civil engineers Rondelet and Dederich. The writer of a history of Rome, published at Boston in 1886, refers to the book of Frontinus as belonging "to the class which furnish facts without giving ideas." If, however, Frontinus be read carefully by those who are able to understand the facts, as scientists and civil engineers can do, it appears, as the

English translator well says, that many and valuable ideas may be obtained. The interesting commentaries contained in this volume render it possible for even the general reader to do this with pleasure and profit.

MANSFIELD MERRIMAN.

Gleanings from Nature. By W. S. BLATCHLEY. Indianapolis. 1899. 16mo. 348 pp., 15 pl., 100 cuts.

The State Geologist of Indiana has here given us a dozen or more chapters on the natural history of his State, with the laudable purpose of interesting young people in the objects about them. If but a fraction only of the 800,000 children to whom he dedicates the book will read it, the results should be good; for the author speaks at first hand of all he writes, and seems equally at home whether discoursing of quadrupeds, birds, reptiles, fishes, insects, trees, weeds or caverns, to which latter feature of southern Indiana much space is given. We have noticed but one serious error, where the femora of *Mantis* are taken for tibiæ. The stories are simply told, and derive their chief value from being the outcome of close personal contact with nature and from their local flavor. The book is to be heartily recommended to the young people not only of Indiana but of the neighboring states, to which it is nearly as well adapted. It will take them out of doors on every page and awaken a new interest in living nature. The illustrations are mostly good, many excellent and all to the purpose. There is a sufficient index.

S. H. S.

LIVERPOOL MARINE BIOLOGICAL COMMITTEE'S MEMOIRS.

THE appearance of No. I., of the Liverpool Marine Biological Committee's 'Memoirs on Types of British Marine Plants and Animals,' deserves more attention from teachers and students of natural history than the intrinsic scientific value of the volume, however much this may be, can justly claim. This because of the uniqueness in several ways of the series which this number introduces. In the first place these volumes are to be unique in the matter of price. Who has ever before heard of a bound volume, in the English tongue at least, on a natural history subject, written by a distinguished specialist, and containing fifty pages and four good plates, being sold for 37½ cents? Yet that is the price of this first memoir.

It is written by the editor of the series, Professor W. A. Herdman, and the type treated is *Ascidia*, as might be anticipated from the editor's long and distinguished devotion to the group of animals of which this is a representative.

The series again is well-nigh unique in its origin and purpose. What these are may be best shown by extracting a paragraph from the editor's preface.

"In our twelve years, experience of a Biological Station (five years at Puffin Island and seven at Port Erin), where college students and young amateurs formed a large proportion of the workers, the want has been constantly felt of a series of detailed descriptions of the structure of certain common typical animals and plants, chosen as representatives of their groups, and dealt with by specialists. The same want has probably been felt in other similar institutions and college laboratories."

Some twenty other memoirs of like nature and by nearly an equal number of workers are promised.

It is hardly necessary to say that the number before us is scientifically accurate and up to date. It could hardly be otherwise; for its author has himself contributed more than any one else to the making of our knowledge what it is to-day, of the structure and speciography of the Tunicata. No one is better able than he to write such a book, and he has written it as well as he is able to.

The only instances in which I have noticed any doubtfulness or unclearness of statement are in connection with the pericardium and heart, and the coelom. On page 34 we are told that the "pericardial sac and its invagination the heart have formed in the mesoblast between the endostyle and stomach." A reader not already familiar with ascidian embryology would find difficulty, I should think, in harmonizing this statement with the clear statement of the fact found on page 10, viz.: that the "pericardium [from which the heart itself is produced] and epicardium originate as outgrowths from the archenteron." Comparing the two statements such a reader *might* conclude that the first statement quoted means that the pericardial sac and its invagination are *embedded in* mesoblast as their formation proceeds, but he would also be justified in understanding the one statement to mean that the pericardial sac and hence the heart are of mesoblastic origin, while the other means that they are of hypoblastic origin.

Again the statement (page 10) that the cavity of the pericardium and epicardium 'may be regarded as coelomic spaces' is not exactly clear when compared with the statement made a few lines below on the same page, that the cavities of the renal vesicles and gonads are sometimes interpreted as being formed 'by a splitting of the mesoblast (*coelomic*).'

But the book is an admirable résumé of our knowledge of a typical ascidian, and if the succeeding numbers are equally satisfactory, the series cannot fail to be a potent factor in promoting the study of natural history not only in Great Britian, but as well beyond its borders.

It is unfortunate that the volumes could not be bound a little more securely, for they will hardly withstand the rough usage which they are pretty sure to receive as laboratory guides. If this could not be done without increasing the price, and if the price could not be increased even by a small amount, then it seems to me that it would be better to cut down the text and illustrations, particularly the former, somewhat, and apply the saving in expense thereby to making the binding better.

WM. E. RITTER.

GENERAL.

A LIMITED number of the reports of the University Geological Survey of Kansas still remain for distribution among persons who are interested in mining and geology. The publications to date include five volumes bound in cloth, and two annual reports on the Mineral Resources of Kansas bound in paper. All these may be had for the asking, except Vol. I., the supply of which is entirely exhausted. Persons writing for any or all of the reports should enclose the necessary postage, or request that they be sent by express. The volumes are: Vol. II., General Geology of Western Kansas, postage 26 cents; Vol. III., a Special Report on Coal, postage 28 cents; Vol. IV., Paleontology of the Upper Cretaceous, postage 32 cents; Vol. V., A Special Report on Gypsum and Gypsum Cement Plasters, postage 16 cents; Annual Report of Mineral Resources of Kansas for 1897, postage 4 cents; Annual Report on the Mineral Resources of Kansas for 1898, postage 7 cents.

MESSRS. D. APPLETON & COMPANY have nearly ready for publication *The International Geography*. Seventy authors have collaborated in its production, including the leading geographers and travelers of Europe and America. The work has been planned and edited by Dr. H. R. Mill, who also wrote the chapter on the United Kingdom. Among the authors are Professor W. M. Davis (The United States), Dr. Fridtjof Nansen (Arctic Regions), Professor A. Kirchhoff (German Empire), Mr. F. C. Selous (Rhodesia), Professors de Lapparent and Raveneau (France), Sir Clements Markham, F. R. S. (Ecuador, Bolivia, and Peru), Sir John Murray, F. R. S. (Antarctic Regions), Count Pfeil (German Colonies), Mr. James Bryce, M. P. (The Boer Republics), Sir H. H. Johnston, the late Sir Lambert Playfair, Sir F. J. Goldsmid, Sir Martin Conway, Sir George S. Robertson, Sir William MacGregor, Sir Charles Wilson, F. R. S., the Hon. D. W. Carnegie, Mrs. Bishop, Dr. A. M. W. Downing, F. R. S., Dr. J. Scott Keltie, and Mr. G. G. Chisholm. The book is illustrated by nearly five hundred maps and diagrams which have been specially prepared.

OTHER books announced for early publication by Messrs. D. Appleton & Co. include Comparative Physiology and Morphology of Animals, by Professor Joseph Le Conte; Some Great Astronomers, by Dr. Edward S. Holden, and the Story of Eclipses, by Mr. G. F. Chambers.

SCIENTIFIC JOURNALS AND ARTICLES.

WITH the December number the *American Naturalist* completes its twenty-third volume. Hermon C. Bumpus has the leading article, on

'Facts and Theories of Telegony,' which gives a brief review of the subject in general and of the recent experiments by Professor Ewart in particular. Edward Thorndike in a 'Note on the Psychology of Fishes' tells of a simple experiment by which it was shown that the common Fundulus could readily learn the proper route of escape from the compartment of an aquarium in which it was confined. C. E. Mead discusses '*Collops bipunctatus* as an Enemy of the Colorado Potato Beetle,' concluding that it is an important agent in protecting the potato crop. 'The Egg-Carrying Habit of Zaitha' is described by Florence W. Slater, and Robert T. Edes treats of the 'Relation of the Chirping of the True Cricket (*Oecanthus niveus*) to Temperature,' showing that the rapidity of the chirps increases with the temperature. 'Regeneration in the *Hydromedusa*, *Gonionemus vertens*' is discussed in detail by T. H. Morgan, whose experiments show that, although pieces smaller than one-eighth of the medusa may make new individuals having the medusa form, the remodeling does not include the internal organs. Richard C. McGregor has an article on '*Salvinia coccinea*, an Ornithophilus Plant,' describing the manner in which pollination is effected by humming birds, and the sixth instalment of 'Synopses of North American Invertebrates,' by W. P. Hay, is devoted to the *Astacidæ*. The reviews are numerous, and under Correspondence Henry B. Ward puts in a plea for the use of Mesenchyme.

The *Journal of the Boston Society of Medical Sciences* for December has for its first article an abstract of a paper by Charles S. Minot on the 'Classification of Tissues,' which takes the ground that this should be based on embryological data. W. F. Whitney describes some 'Malformations of the Kidneys,' and Thomas Dwight some 'Remarkable Skulls.' The final article 'Experiments on *Saphrolegnia ferax*, and their Application to the Trout Hatchery,' by J. H. Cunningham, Jr., is of much interest to fish culturists.

The Osprey for December opens with some 'Notes from Northern Counties of California,' illustrated by Milton S. Ray; this is followed by a reprint of J. E. Harting's article on 'The Largest Bird that Flies,' which is the subject of some interesting editorial comment. There is a brief biographical sketch, with portrait, of the late D. W. Prentiss. The editorial columns contain a description of the recent meeting of the American Ornithologists' Union, and among the letters is the prospectus of the Third International Ornithological Congress, to be held in Paris during the coming year, and a record of the bird arrivals at Dawson.

SOCIETIES AND ACADEMIES.

NEW YORK ACADEMY OF SCIENCES. SECTION OF GEOLOGY AND MINERALOGY.

At a meeting of the section on December 18, 1899, in the absence of the Chairman, Professor J. J. Stevenson was elected temporary chairman. Twenty-six persons were present.

Professor J. F. Kemp presented a paper on 'Recent Theories Regarding the Cause of Glacial Climate.' During the subsequent discussion of this paper by Professors R. E. Dodge, D. S. Martin and others, Professor Stevenson called attention to the fact that the great excess in the area of the peat bogs on the surface of the earth, during the present period, over that of the swamps which prevailed during the Carboniferous, shows the little foundation for the hypothesis of an excess of carbon dioxide in the atmosphere during the formation of the coal. Dr. Julien also pointed out, in reference to the theory of the refrigerating influence of the absorption of carbon dioxide from the atmosphere, during the decay of rocks, that this effect may have been more than offset by the heat produced during the accompanying absorption of oxygen.

Professor Kemp then read a paper on 'Metamorphosed Dikes in the Mica Schists of Morningside Heights.' This paper was discussed by several members. Dr. Julien acknowledged the resemblance of this outcrop of black hornblende schist to a sheared dike, produced by its strong contrast in color with the enclosing light gray micaceous gneiss, and by the sharp lines of separation of the schist from the highly tilted beds on either side, as if thrust up from below. Yet this is but one of hundreds of exactly similar outcrops in New York and Westchester

Counties. All are intercalated, however, as thin beds in the Manhattan Series; in not a single case has a hornblende schist been observed to cross the other beds. If one or all of these are dikes, the lamination of the associated beds must also have been effected by a general shearing. But the series is accepted as typically metamorphic, a succession of true beds of altered sandstone (quartzitic gneiss), shales (mica schist), magnesian schists (dolomite marble), etc., into which the injection of trap dikes exclusively between the beds would be entirely improbable. These hornblende schists, moreover, on Morningside Heights, as elsewhere, thin out along the strike like the other lenticular beds, often become partially or entirely biotitic and quartzose, passing gradually into biotitic schists, biotitic and hornblende gneisses, exactly like those of acidic constitution which enclose the above supposed dike. Indeed, a basic element, rich in lime and magnesia, is distributed throughout the Manhattan Series, and was originally perhaps hornblendic throughout, or, in the absence of silica, concentrated in the numerous dolomite beds. The more purely hornblendic layers correspond in composition, as shown by the interesting analysis in the author's paper, to beds of altered marl; their density has enabled them to resist and escape, in the present surviving layers, the biotitic alteration which has affected the general series.

A paper was then presented with lantern illustrations by Mr. W. D. Matthew, 'Notes on the Geology of the Laramie Plains and Rattlesnake Mountains in Wyoming.' Professor H. F. Osborn remarked on the uncertainty of the age of the *dinosaur*-beds, whether Jurassic or Lower Cretaceous. All determinations hitherto have been made by collectors, but neglected by the paleontologists, though the section is here continuous from the Mountain Limestone of the Carboniferous up to the base of the Cretaceous. Nor has the correlation yet been made with the corresponding beds of the Wealden, Purbeck, etc., of England and the European Continent. The æolian theory of the author, however, does not appear consistent with reported observations of remains of aquatic life in these beds. The Chairman stated that no true Mountain Limestone fossils have yet been detected in the bed so called in Wyoming, nor the good evidences yet needed of Jurassic life in the *dinosaur*-beds, of other vertebrate life, lacustrine remains, etc., of that age, and for confirmation of synchronism of Jurassic life between the continents. As to the heavy oils of Wyoming, they contain but little paraffin and perhaps less than twenty per cent. of kerosene, and are likely to be worthless, except possibly hereafter for use as a coarse fuel. The paper was further discussed by Professors Dodge, D. Van Ingen and others.

ALEXIS A. JULIEN,
Secretary of Section.

THE ANTHROPOLOGICAL SOCIETY OF WASHINGTON.

THE 297th regular meeting of the Society was held Tuesday evening, December 19, 1899.

Mrs. M. C. Stevenson read a paper on 'Zuni Games,' in which several ceremonial games were technically described, and the errors of other observers and writers pointed out. The author claimed that these errors were due to a superficial acquaintance, not only of the game itself, but to the lack of familiarity with the people and their language. It was necessary to live a long time with them in order to discover the true meaning of many of the details.

Dr. J. H. McCormick read a paper entitled 'The Supernatural in Primitive Concept,' in which he traced the origin and development of primitive ideas of religion and pointed out the four universal primitive doctrines of Physianthropy, Animism, Transmigration and Anthropomorphism, and the influence exercised by each upon such concepts.

Mr. George R. Stetson gave 'Some Curiosities of Philological Literature.'

Mr. Stetson examined the literature of Comparative Philology from the point of view of the student "who is disturbed if not somewhat appalled by the prevailing confusion and contradictions in the understanding and application of the technical terms used by philologers."

In behalf of the inquirer whose mental vision is obscured by the divergent concepts and theories advanced by the various professional writers in regard to the origin of speech, and the genesis, formation, growth and classification of language, Mr. Stetson appealed to the latter to exercise greater care in announcing, and greater diligence in seeking for unanimity in their concepts.

He suggested that, in order to prevent the existing confusion among professional writers as well as among students, it was imperative that a line be drawn and a classification adopted which shall definitively separate the crude, fluctuating, undeveloped, and unrefined speech of a narrowly circumscribed region—*i. e.*, the 'dialectic stage'—from the comparatively fixed and highly developed inflected speech of an extensive area, or the 'cultivated stage.'

That patois and dialect should cease to be used as synchronal or equivalent terms, as in the history of language the former represents the destructive and the latter the constructive period.

That the use of 'dialect' as a relative term, by which the meaning of the 'dialect' and 'language' is made to depend upon the connection in which the terms are used should be abandoned, in the interest of clear thought and intelligible classification.

That writers should more particularly differentiate 'speech' from 'language,' and, in comparative philology, the study of the affinities of language, from linguistics, the study of the derivation of words.

That the classification and relations of dialect, language, patois, and jargon be more absolutely defined and rescued from their present confusion by some authoritative body.

That the aim of writers on comparative philology and experts in linguistics should be to more completely separate the conceptual and hypothetical from the practical and profitable, and thus prevent the needless waste of thought and effort.

"That more is to be learned from analogy and living speech, as Professor Sayce suggests, than from dead literature," or it may be added from the questions of origin and precedence.

In conclusion Mr. Stetson remarked that he did not wish to convey the impression that the absence of unanimity in concepts and confusion in terminology is peculiar to the writers on philology; he feared that they might be found in a greater or less degree in all philosophical inquiries.

He also expressed the opinion that students generally, in view of the prevailing contradictions, the dearth of recorded facts, and superabundance of hypotheses, are not inclined to accept without question the present claim of comparative philology as a science, and that while extremely valuable work has been and is being done,—especially in the division of linguistics, a study which has been practically born within our memory,—its essays and instruction are too frequently founded upon hypotheses "which furnish no perceptible evidence of truth or of value in their practical application."

J. H. McCormick,
Secretary.

DISCUSSION AND CORRESPONDENCE.

HOMOLOGIES OF THE WING VEINS OF HYMENOPTERA.

Very important investigations of the morphology of the venation of the wings of insects have recently been made by Professor Comstock in his 'Manual for the Study of Insects,' published in 1895, and more recently by Comstock and Needham, in a series of articles published in the *American Naturalist*, 1898–99, reissued as a pamphlet of 124 pages and 90 figures by the Comstock Publishing Company.

While I accept their principles, the application of them and a comparison of the figures lead me to a different conclusion with regard to homologies of the wing-veins of hymenoptera, which in connection with my studies of the bees it has been very important for me to work out. In the Manual vein M is regarded as three-branched, as in the diptera, but in the later articles this vein is regarded as four-branched.

In the first place I regard the wing of *Macroxyela* (Manual, p. 606, fig. 705) as a better example of the typical hymenopterous wing than the composite wing produced by a combination of the wing of *Macroxyela* and *Pamphilius* (*Am. Nat.*, 414; figs. 38–39). But the latter will illustrate my views.

My conclusions are: that the cross-vein m connects M_2 and $M_3 + Cu_1$, as in the wing of

Pantarbes (40) and *Rhamphomyia* (41), and that the cross-vein marked *m — cu* in *Leptis* (*Am. Nat.*, 32; 337, fig. 30) does not exist in the hymenoptera, but is obliterated by the coalescence of the above-mentioned veins; M_4 is Cu_1, and Cu_1 is Cu_2; the cross-vein marked *m — cu* is not homologous with the one so marked in *Leptis*, but belongs to the *arculus!* To account for the vein marked Cu_2 I should say that it is before the arculus and does not enter in the consideration of the ordinary cases. According to the authors, this vein does not occur in any of the hymenoptera, except *Pamphilius*.

If my view is correct, a large part of the peculiarities of the venation of hymenoptera is connected with the great lengthening of the arculus and the shifting of it from the base of the wing.

The only changes in the designation of the cells which my attempt at elucidation involves are: M_3 is Cu_1; Cu_1 is *2nd Cu; Cu* is *1st Cu; M* is homologous with the cell marked *1st M* in *Scenopinus* (*Am. Nat.*, 32; 339, fig. 36); M_4 is the same as the cell marked *2nd M* in *Scenopinus* and the cell marked *M* in *Rhamphomyia* (41).

CHARLES ROBERTSON.

NOTES ON INORGANIC CHEMISTRY.

A GOOD illustration of how much material there is in inorganic chemistry which needs reinvestigation, is found in the fact that there has been no general method of forming the sulfids of the rare earths, nor have any of the sulfids been obtained in a pure condition, with the possible exception of that of cerium. This gap has now been filled by Muthmann, of Munich, in conjunction with L. Stützel. They find that while the oxids are very slowly converted into sulfids when heated in a stream of hydrogen sulfid, the anhydrous sulfates are, under the same conditions, very readily converted quantitatively into the sulfids. The sulfids of cerium, lanthanum, neodymium and praseodymium were formed in this way, and their properties, physical and chemical, studied. They are fairly stable in the air at ordinary temperature, but are decomposed with evolution of hydrogen sulfid by warm water or dilute acids. They take fire readily on heating in the air, and when finely divided the cerium sulfid often proved pyrophoric. They burn to a mixture of oxid and sulfate. On heating in a current of dry hydrochloric acid, they are readily and quantitatively converted into the anhydrous chlorids, and on a small scale this is the best and easiest method of preparation of these chlorids. The study as a whole, which is published in the last *Berichte*, is a valuable contribution to the chemistry of the rare earths.

IN a series of experiments by A. Petterson, of Upsala, printed in the *Klinische Wochenschrift* (Berlin), the fact is established that in meat and fish preparations, containing 15% of salt for the purpose of preservation, a constant and luxuriant growth of microörganisms takes place. From this the conclusion is drawn that the special flavors, odors, consistencies, and colors of salt conserves are chiefly produced by various microörganisms.

THE subject of food preservatives is also discussed from a different standpoint by R. Kayser, of Nuremberg, in the *Zeitschrift für öffentliche Chemie*. In earlier times, the tendency of various foods to decomposition was counteracted by drying, smoking, pickling and the like. In some cases special processes were used, as the treating wine with sulfur, beer with hops, etc. At the present day, scientific progress has led to the use of low temperatures, of sterilization, and especially to the use of chemicals. In this last case the demand is made that the preservatives used shall not only be harmless in the quantities used, but inert to the human system even in vastly greater quantities than ever used in foods. This demand, it is pointed out, is unprecedented, for it is not complied with under old methods. Common salt, saltpeter and creosote are present in these and are not less injurious in quantity than the more recently used boric acid, borax, salicylic acid, benzoic acid, etc. There are no authentic instances on record of injury from the use of any of these in foods, while there are very many instances of injury from foods which, apparently good, were in reality decomposed (presence of ptomains, etc.). The whole subject needs to be treated in a more rational way.

The latest numbers of the *Chemical News* contain reprints of several papers on the new radiant substances discovered by M. and Mme. Curie. It is found that the radio-activity of polonium and radium can be communicated by contact to inactive bodies, such as many metals, paper, barium carbonate and bismuth sulfid, and this induced radio-activity persists for a considerable time.

Mme. Curie has concentrated by fractionation the radium which is associated with barium in the uranium minerals, and determined the atomic weights of the successive fractions—one fraction having an activity 3000 times that of uranium had an atomic weight of 140. (Ba = 137.8.) A later fraction of 7500 times uranium's activity had an atomic weight of 145.8, hence it seems that radium has a higher atomic weight than barium. In this work half a ton of uranium mineral was used and the radiferous barium chlorid which was fractionated amounted to two kilos. The spectrum of this concentrated radium was studied by Demarçay, and in addition to the spectrum of barium, very intense and complete, a series of new lines was found and measured. Some of these are very characteristic. It thus appears reasonably certain that radium has a definite position as a chemical element, and the properties of the purified substance will attract great interest when determined. Among the chemical effects of the salts of radium is the conversion of oxygen into ozone. This phenomenon seems to be connected rather with the radio-activity than with luminosity. Radium carbonate is very luminous, but produces less ozone than radium chlorid, which is much less luminous, but more strongly radio-active. If a radium salt is placed in a glass vessel, a violet coloration is seen in the glass which proceeds from the interior to the exterior. In ten days or so the bottom of the flask is almost black. This takes place in glass containing no lead. The effect of the Bacquerel rays upon barium platino-cyanid is also chemical. All these phenomena point to the fact that the rays emitted by radium present a continual development of energy.

J. L. H.

CURRENT NOTES ON METEOROLOGY.

THE WEST INDIAN HURRICANE OF AUGUST, 1899.

An account of the West Indian hurricane of August 7–17 last, in the *Monthly Weather Review* for August (issued October 30), brings out several points worth noting here. The report from the Weather Bureau observer at Arroya, Puerto Rico, says that the Spanish steamship *Alava* took refuge in the Port of Jobos, and with all her anchors down and working full speed ahead, she dragged for half a mile. At Aguadilla, Puerto Rico, the passage of the calm central 'eye' of the storm occupied about one hour. At Nassau, considerable damage was done by the northeast wind, which backed to northwest, and fell calm. People then came out to gather up their scattered effects, when the wind suddenly began to blow from the southwest with great force. An aneroid reading of 27.75 inches, corrected for instrumental error and for elevation, was made at Guayama, Puerto Rico, and one of 28.11 inches was made at Juana Diaz.

RECENT PUBLICATIONS.

Note.—The unusually large number of recent publications of importance makes it necessary, in view of the limited space, to restrict our mention of them to a few lines only.

Evelyn B. Baldwin: 'The Meteorological Observations of the Second Wellman Expedition,' *National Geographic Magazine*, December, 1899, 312–316. Mr. Baldwin is an official of the United States Weather Bureau, and was equipped with instruments by the Bureau. This is a preliminary report of his meteorological work.

Frank H. Bigelow: 'The probable State of the Sky along the Path of Total Eclipse of the Sun, May 28, 1900, Observations of 1899,' U. S. Department of Agriculture, Weather Bureau. Bulletin No. 27. 8vo. Washington, D. C., 1899. Pp. 23. Charts IV. This report summarizes, for the information of astronomers and others interested in the approaching eclipse, the results of observations made in 1897, 1898 and 1899 to determine the prevailing average cloudiness in the districts covered by the eclipse track.

Frank H. Bigelow: 'Some of the Results

of the International Cloud Work for the United States,' *American Journal of Science*, December, 1899, 433–444. A preliminary statement of results which are soon to be published *in extenso* by the Weather Bureau.

OLIVER L. FASSIG: 'Types of March Weather in the United States,' *American Journal of Science*, November, 1899, 319–340. A discussion of the relations existing between the mean atmospheric pressure, the prevailing character of the weather and the paths of storms.

WILLIS L. MOORE: 'Report of the Chief of the Weather Bureau for 1899,' U. S. Department of Agriculture, Weather Bureau. 8vo. Washington, D. C., 1899. Pp. 23.

B. S. PAGUE: 'The Mild Temperature of the Pacific Northwest, and the Influence of the Kuro Siwo.' 8vo. Portland, Ore., 1899. Pp. 11. Charts III. The author classifies the temperature conditions of the north Pacific Coast into continental, dynamic and oceanic types. He believes that dynamic heating of descending air is more effective than the influence of the ocean in producing the mild winter temperatures of the Pacific Northwest.

R. DEC. WARD.

HARVARD UNIVERSITY.

RECENT ZOOPALEONTOLOGY.

Adaptive radiation of the Camels and Llamas.—Professor Scott advances the following hypothesis in his recent important memoir:

"The most interesting and striking result to which the study of the Uinta selenodonts has led is the very unexpected conclusion that, with the possible exception of the *oreodonts* and *agriochoerids*, all of the strictly indigenous North American *selenodonts* are derivatives of the tylopodan stem. Paradoxical as this conclusion may appear, I believe it to be fully justified by the evidence which will be laid before the reader. The Tylopoda are thus seen to be a very ancient and highly diversified group, comparable in this respect to the Pecora, or true ruminants, which they so closely resemble in many features. The Pecora are an Old World group, which underwent great expansion and diversifications in Eurasia, but did not reach this continent till late Miocene times, and never attained the importance here that they have so long had in the Eastern Hemisphere. Their place was, to a very great extent, taken in America by the Tylopoda, which ran a course of development in many ways parallel to that of the Pecora and Tragulina, but with a variety and diversity of structure, habit, and appearance, such as are not attained in either of the latter groups." It has long been known that the Camels and Llamas had their home on this Continent, but Professor Scott's hypothesis, that practically all the American Artiodactyls, except the pigs, sprang from a common cameloid stem, is of the greatest interest. If confirmed, it will take rank as a brilliant generalization resulting from recent exploration. Even if not confirmed, it will be of great value as stimulating closer inquiry into the natural relationships of the American even-toed Ungulates. *Trans. Wagner Free Institute*, Phila., May, 1899, Vol. VI.

The Pliocene Hyrax.—*Pliohyrax* Osborn is identical with *Leptodon* Gaudry. This rather dry announcement relates to an interesting extension of our knowledge of the Hyracoidea. For some years a skull found upon the Island of Samos awaited description in the Stuttgart Museum; Professor Fraas kindly placed it in the hands of Professor Osborn, who described it before the International Zoological Congress, at Cambridge, as a new and very remarkable form of *Hyrax* from the Lower Pliocene, as the only fossil representative of this order and as belonging to a distinct family of Pliohyracidae and a distinct genus *Pliohyrax krupii*. It now appears that the lower jaw found by Professor Gaudry in Pikermi, Greece, and long known as *Leptodon graecus* belongs to the same type as the above. Dr. Max Schlosser, of Munich, points this out in an interesting article in the *Zoologischen Anzeiger* of October. He leaves the animal among the Hyracoids and suggests that it is of South American origin, a suggestion of considerable probability and of very great interest.

Exploration for Dinosaurs.—Great activity prevailed last season in the search for the remains of Dinosaurs. A report of the parties exploring in the Dinosaur beds under the direction of Professor W. C. Knight has already been made in this JOURNAL. In addition to the scattered fossils thus secured by representatives of many institutions, there were five fixed parties in the field. The three representing the Field Columbian Museum, the University of Wyoming, and the University of Kansas had their quarries in the Freeze Out Mountains. A few miles to the east was the Carnegie Museum party under the direction of Dr. Wortman; they found a very promising locality in which a large portion of a skeleton of Diplodocus was secured. To the southeast was the American Museum party, which continued the excavation of the 'Bone Cabin Quarry' with good results, and four miles west of this point secured a considerable part of a Brontosaur skeleton. In the quarry itself the greater portion of a Mososaur skeleton was found in a very much crushed condition. Altogether the general work of the season will greatly advance our knowledge of the Dinosaurs. At the same time the beds in the Como region have been so thoroughly explored that it is becoming very difficult to find these animals, and when found it is very difficult to take them out.

Ear bones of Marsupials.—According to Richard Weil,* the ossicula auditus of the opossum are not at all parallel in their development with those of the pig, considered as a representative of the Placental mammals. This tends further to confirm the conclusion, arrived at from many other grounds, that Marsupials are entirely to be regarded as forms parallel to the Placentals rather than as ancestral forms. As regards the origin of the malleus, Weil's investigation confirms the prevailing opinion that it is derived from Meckel's cartilage or the mandibular arch. The incus also arises from the mandibular arch and has no relation to the hyoidean arch. Mr. Weil believes that Kingsley has placed too much dependence upon the relation of the nerves to these elements. Weil's results directly contradict the theory of Reichert, Huxley and others, that the quadrate of the Sauropsida is represented in the auditory chain of Mammals, for according to his observations the quadrate belongs not to the mandibular arch from which the Mammals derive their ear bones but to the palatoquadrate bar.

* *Annals N. Y. Acad. Sci.*, Vol. XII., No. 5. Pp. 103 to 118, July 7, 1899. 'Development of the ossicula auditus in the opossum.'

The Fins of Ichthyosaurus.—Professor Fraas, of Stuttgart, describes the most perfect specimen of an Ichthyosaur which has yet been found in the famous quarry in Holzmaden. It exhibits in a remarkable manner the structure of the fins, having been worked out with the utmost care by Herr Bernhard Hauff for the Royal Geological Museum of Hungary. Although partly described by Owen, the complete dermal structures of Ichthyosaurs were first discovered in the Holzmaden quarry in 1892. Five specimens have been found altogether in a somewhat restricted part of the quarry. The skin impressions are of a light brown to a deep black color with a grayish slate blackground, and are so fine that they must be exposed with the greatest skill by the use of a fine scapel working under a magnifying lens. The specimen here described gives a perfect picture of the dorsal and caudal fins and of the fin folds surrounding the paddles. The irregular folds behind the dorsal fin represent a displacement of a portion of the pigmented skin from the sides of the body. The caudal fin is remarkable in the elongation of its upper lobe, but it is not at all evident how this lobe was supported, since, unlike the sharks, the tail vertebræ turn down into the lower lobe.

H. F. O.

*AGRICULTURAL EXPERIMENT STATIONS.**

THE most obvious indication of the success of experiment stations as a means for improving agricultural conditions in this country is the steady increase in the number of stations and station officers, and in the amount of financial support which they have received from the National and State governments. In the first volume of the *Record* it is stated that in 1889 there were 46 stations in the United States, receiving an aggregate revenue of about $725,000, of which $600,000 was appropriated from the National Treasury and $125,000 was received from State governments and other local sources. The total number of persons engaged in the work of the stations and at this office that year was 402. In 1898, the last year for which statistics have been compiled, the total number

* From *Experimental Station Record.*

of stations was 54. Their total income was somewhat over $1,200,000, of which $720,000 was received under the Hatch Act (in addition to $35,000 for this office) and $480,000 from State governments and other local sources. The number of officers had increased to 669.

With the increase in the number of the stations and the enlargement of their resources, there has been a corresponding increase in the number and variety of their publications, and these have been more thoroughly distributed each year. Besides the vast amount of agricultural information which has thus been generally diffused among our farmers, either directly through station publications, or indirectly through the public press, more than fifty books on strictly agricultural subjects have been written by station men during the past ten years, and the results of the work of the stations are being largely incorporated in books whose authors are not connected with the stations. It requires only a superficial retrospect to discover a very remarkable difference in the freshness of material and the thoroughness of treatment of the published information available to our farmers ten years ago and that which is at their command to-day. It is most encouraging to observe that, despite the pessimistic predictions in certain quarters, the output of carefully prepared books for the farmer's use has notably increased within the past few years, and American books for the American farmer are written from an American standpoint, and on the basis of accurate information obtained by American investigators.

SCIENTIFIC NOTES AND NEWS.

WE regret to record the death in New York on January 15th of Dr. Thomas Egleston, emeritus professor of mineralogy and metallurgy in Columbia University.

AT the January meeting of the American Academy of Arts and Sciences, Boston, Professor William M. Davis was chosen corresponding secretary in the place of Mr. Samuel H. Scudder, resigned.

M. MÉRAY has been elected a correspondent of the section of geometry of the Paris Academy of Sciences.

PROFESSOR RÖNTGEN, who has accepted the call to the University of Munich, has been appointed director of the State Institute of physics and metrology.

MR. W. N. SHAW, of Emanuel College, Cambridge, has been chosen to succeed Mr. Scott at the British Meteorological Office.

MM. RADAU AND BIGOURDAN have been presented by the Paris Academy of Sciences to the Minister of Public Instruction, who will select one to fill the vacancy in the Bureau des Longitudes, caused by the death of M. Tisserand.

PROFESSOR G. FREDERICK WRIGHT, of Oberlin College, has been given a leave of absence for a year and three months. He will make geologic studies in the Sandwich Islands, Japan, Russia, Egypt, Italy and other countries.

ON the twenty-fourth of December, 1899, the Physico-Mathematic Society, of Kazan, Russia, celebrated a jubilee in honor of the twenty-fifth year of professorial and scientific service of its President, Professor A. Vasiliev. It is also the fifteenth year of his presidency. Professor Vasiliev has been an important figure in Russian science. His discourse on Lobachevski has been translated into English by Professor Halsted, and a German translation of his book on 'Tchebychev' is to be published this month by Teubner at Leipzig. The first volume of an edition of 'Tchebychev's Collected Works,' in French, has just appeared, edited by the Academicians Markof and Sonine. It contains a fine portrait of the great mathematician and the first thirty-four memoirs of Vasiliev's list.

THE two books, Whitehead's 'Universal Algebra' and Killing's 'Einführung in die Grundlagen der Geometrie,' which were particularly signalized in Professor Halsted's Report on Progress in Non-Euclidean Geometry recently published in this JOURNAL, have been entered in competition for the Lobachevski prize of 1900.

THE American Society of Naval Engineers has awarded its first prize for the best technical essay submitted to Professor W. F. Durand of Cornell University, for his paper on 'Electrical Propulsion for Torpedo Boats.' The prize consists of a substantial compensation, life membership in the Society, and a gold medal. The second prize has been awarded to D. C. Ball, late of the Engineer Corps, and now a consulting engineer in New York, for his paper on 'Interior Diagrams for Multiple Expansion Engines.'

THE University of Lyons has received a legacy of 50,000 francs for the establishment of a prize to be awarded every five years to a resident of the city or neighborhood who shall have contributed to the advancement of hygiene or medicine.

M. BISCHOFFSHEIM has given to the Paris University the observatory established by him at Nice at a cost of 2,500,000 francs, together with an endowment of the same amount.

THE government has appropriated 13,000 Marks for mounting the 12-inch photographic telescope presented to the University of Heidelberg. Two thousand Marks have been given to the Scientific Society of Heidelberg for publication.

ANDREW CARNEGIE has promised the College of Emporia, Kan., $50,000 for a library building as soon as the present debt is paid.

DR. DOMENIK JOSEPH RITTER VON HAUSCHKA, formerly professor of medicine at Vienna, has died at the age of 84 years.

AT the last meeting of the Council, the Ottawa Field Naturalists' Club, Dr. Ami in the chair, the following gentlemen were nominated a committee of the Club on the Billings Memorial: Mr. J. E. Whiteaves, Sir James Grant, Dr. James Fletcher, Mr. Walter R. Billings, Mr. Byron E. Walker (Toronto), Mr. W. J. Wilson (Secretary of the Club), and Dr. H. M. Ami. A handsome sum of money has already been subscribed, and it is confidently expected that sufficient funds will be raised to pay suitable tribute to the memory of one who has done much to advance researches in paleontology and natural history in North America.

THE report of the Executive Committee of the New York Zoological Society shows that the Society has a total membership of 736, an increase of 136 over last year. The committee during the last year added $49,760 to the Park's fund, making $160,779 in all. The City had, however, cut the Society's allowance to $40,000 from $60,000. It was stated that the most pressing needs of the Society for new buildings could be met for $75,000. The following were elected members of the Board of Managers of the class of 1904: Ex-Gov. Morton, Andrew Carnegie, Morris K. Jesup, John L. Cadwalader, Philip Schuyler, John S. Barnes, Madison Grant, William White Niles, Samuel Thorne, H. A. C. Taylor, William D. Sloane, and Hugh J. Chisholm.

THE report of the Palisades Commission, which has been in communication with a similar commission from New Jersey, was made to Governor Roosevelt at Albany, on January 12th. It presents a bill providing for an appropriation of $250,000 to the National Government for Palisades Park purposes, in addition to land ceded in Rockland County. "While New York has a vastly greater material interest in the preservation of the natural scenery of the Palisades than has New Jersey," the commission says, "the former has offered to the National Government only an unimportant contribution in its very limited length of water front on the Hudson, while the State of New Jersey has offered to give property valued at upward of $750,000. It seems equitable that New York should tender in money what she lacks in land. With such an equalization of the burden, it is deemed not unlikely that all three parties may be brought into harmony in the carrying out of the proposition to preserve the Palisades."

THE sixth annual series of University Lectures in Biology, at Columbia University is being given by Professor Thomas H. Morgan, of Bryn Mawr College, on the subject of 'Regeneration and Experimental Embryology.' The dates and subjects are as follows: Jan. 16th, General Phenomena of Regeneration; Jan. 19th, The Conditions that Influence Regeneration; Jan. 23d, Special Problems of Regeneration and Development, Specification of the Tissues; Jan. 26th, Development of the Egg in the Light of Experimental Embryology; Jan. 30th, The Relations of Growth, Development and Regeneration. The lectures are given at 5 p. m. in Schermerhorn Hall. No tickets are required.

POSITIONS of library clerk in the Department Division of Forestry and of associate ethnologic librarian in the Smithsonian Institution will be filled by Civil Service examination during February. The position of assistant and expert in forestry history, at a salary of $1000 per annum, will also be filled in February as the result of an examination. Details regarding these, as of all other Civil Service examinations, can be obtained by addressing the U. S. Civil Service Commission, Washington, D. C.

AN examination will be held on February 6th for the position of draughtsman in the Geological Survey. The candidates should have experience in the preparation of drawings of invertebrate fossils.

THE Civil Service Commission of New York State will hold open competitive examinations on or about January 27, 1900, in various cities throughout the State, for the position of chemist, State Board of Health, with a salary of $125 per month. The examination will consist entirely of practical questions relating to analysis of food products, and questions relating to experience and training of the candidates; candidates having applications on file will be given ample notice of the time and place of examination most convenient to their places of residence.

A STATE department of Trade, Art and Commerce has been established for the Russian Empire.

THE Liverpool School of Tropical Medicine proposes to organize an International Conference on Malaria.

A CONGRESS on Tuberculosis will take place at Naples in the spring of 1900. The Congress, in connection with which there will be a great hygienic exhibition, is under the patronage of the Queen of Italy. Professor Baccelli, Minister of Public Instruction, will preside. A German committee has already been formed to assist in making arrangements for the Congress.

WE learn from the London *Times* that several prominent English medical men have been staying in Rome for some days. They visited the scientific and academic institutions and devoted special attention to the researches of Professors Grassi, Bignami, Celli and Dionisi, in connection with malaria. Arrangements were made for the maintenance of continual intercourse between the Roman School of Hygiene and the London School of Tropical Medicine. The English doctors visited various hospitals and conferred with the Minister of Public Instruction, who promised to be present at the official inauguration of the tropical school in London.

AT the annual meeting of the New York Neurological Society, held January 2d, the following officers were elected: *President*, Frederick Peterson; *First Vice-President*, Joseph Collins; *Second Vice-President*, L. Stieglitz; *Recording Secretary*, Pearce Bailey; *Corresponding Secretary*, Lewis A. Conner; *Treasurer*, Graeme M. Hammond; *Councillors*, C. L. Dana, M. A. Starr, B. Sachs, E. D. Fisher and J. Arthur Booth.

AT a meeting of the Zoological Society of London, on December 17th, Dr. P. L. Sclater, the secretary, read a report on the additions that had been made to the Society's menagerie during the month of November, 1899, and called special attention to two snake-fishes (*Polypterus senegalus*) from the river Gambia, obtained by Mr. J. S. Budgett, F.Z.S., during his recent expedition to the Gambia, and presented by him on November 22d. These were believed to be the first examples of this fish ever brought alive to Europe.

THE German Emperor began an address to the officers of Berlin garrison on January 1st with the words: "The first day of the new century sees our army," etc., and the day has been celebrated in Berlin as the first day of the twentieth century.

UNIVERSITY AND EDUCATIONAL NEWS.

BY the will of the late Dorman B. Eaton, Columbia University receives $100,000 to found a professorship of municipal science and administration, and Harvard University $100,000 to endow a chair in the science of government.

MR. LOUIS H. SEVERANCE, of New York City, has given $60,000 to Oberlin College for a chemical laboratory. The provision made for the College by Mrs. C. E. Haskell amounts to $77,000.

DR. ALONZO E. TAYLOR, who, as we recently announced, has been called from the William Pepper Laboratory of the University of Pennsylvania to the professorship of pathology in the University of California, is at present in Berlin arranging for the purchase and construction of instruments for the new laboratories. Mrs. Hearst has provided for the equipment of the department of pathology, including bacteriology, general and special morphological pathology, and pathological chemistry, as also microscopes for the department of anatomy. The equipment of the department of pathology will be very complete and will provide especially for research work.

The sum of 17,000 Marks has been appropriated for apparatus for the new physical laboratory at Breslau.

The bequest of $25,000 by the late E. F. Holden to Syracuse University will be used for the department of astronomy and for the observatory.

Owen's College, Manchester, receives £1000 from the will of the late P. G. J. Ermen.

The medical faculty of McGill University is arranging courses on legal medicine and public health.

The College of Science of the University of Illinois has issued a circular offering a four years' course in natural science, the special object of which is to prepare for work in economic entomology. The principal studies of this course are three years' work in entomology (the last of which will be practically original research carried on under general supervision and advice), a year of chemistry, a half year of physics, mathematics and drawing, two years of German and one year of French, half a year of agriculture (agricultural crops), a year of horticulture (a three-fifths course), and a half year each of elementary biology, invertebrate zoology, human physiology, general botany, bacteriology and geology. To these are added, as minor courses, the military physical training, and rhetoric required for graduation. The courses in agriculture, horticulture and botany are so selected as to give the kind of knowledge and experience especially needed by the economic entomologist, and those in elementary biology and general zoology lay a foundation of training and instruction for the special studies of the entomological course. Students graduating from this course will receive the degree of B. S. in natural science.

The attendance of regular students at the University of Berlin this winter is 6478, which is an increase of 605 students over the registration last winter. The increase is the largest in the faculties of philosophy and law. The University of Berlin has more than three times as many students as it had twenty-five years ago.

The Rev. B. L. Whitman, D.D., since 1895 President of Columbian University, Washington, D. C., has resigned to accept the pastorate of the Calvary Baptist Church in Philadelphia. Dr. Whitman's resignation will take effect on June 1st, next.

Benjamin Lincoln Robinson, Ph.D., has been appointed Gray professor of botany at Harvard University.

Dr. Hans Stobbe has been promoted to an associate professorship of chemistry at Leipzig.

Dr. Luther has qualified as docent in physical chemistry at Leipzig and Dr. Ley in chemistry at Würzburg.

The Degree Committee of the Special Board for Physics and Chemistry, at Cambridge University, are of opinion that the work submitted by Richard Smith Willows, of Trinity College, advanced student, comprising papers (1) On the Variation of the Resistance of certain Amalgams with Temperature (*Phil. Mag.*, November, 1899); and (2) On the Distance between the Striæ in the Positive Column and other Phenomena connected with the Discharge, is of distinction as a record of original research.

Dr. J. Frischauf, professor of mathematics at Graz, has been suspended, apparently for criticising his colleagues in the newspapers.

The New York *Medical Journal* states that Dr. S. L. Schenk, professor of embryology and histology, and director of the Embryological Institute at the University of Vienna, has been retired on a pension. This action is in answer to a petition of the medical faculty of the university alleging the publication in the lay press of scientific theories constituting a form of advertisement. Dr. Schenk, it will be remembered, published a saccharine theory of sex production. He had been a director of the Embryological Institute for twenty-six years.

CONTENTS:

MSS. intended for publication and books, etc., intended for review should be sent to the responsible editor, Professor, J. McKeen Cattell, Garrison-on-Hudson, N.Y.

THE INTERNATIONAL ASSOCIATION OF SCIENTIFIC SOCIETIES.

WE are able to publish through the courtesy of the President of the National Academy of Sciences, Dr. Wolcott Gibbs, the correspondence arranging for the conference of Scientific Societies held at Wiesbaden on the 9th and 10th of October, 1899. We hope to be able to publish later through the courtesy of Professor H. P. Bowditch, delegate from the National Academy of Sciences, an account of the Conference based on the official proceedings. It is scarcely necessary to call attention to the great importance of the plans of the Conference for the advancement of science and for the good understanding between nations to which the advancement of science is largely contributing.

THE ROYAL SOCIETY, BURLINGTON HOUSE,
LONDON, W., April 14, 1899.

SIR: The Royal Society has frequently had occasion to take action in respect to scientific undertakings calling for the coöperation of several countries, and undertakings of this nature show a tendency to increase. The experience of the Society has lead to the belief that it would be very advantageous to the interests of science generally if some machinery could be devised, by means of which suggestions made for international coöperation in scientific enquiries could be thoroughly discussed by the leading men of science from a purely scientific point of view, before definite proposals are made with a view to official action by the Governments of the countries concerned.

With this view, the Royal Society has communicated with the leading scientific Academies of Europe, whose replies give much encouragement to the idea that it may be possible to establish an organization, under which formal and regular meetings of representatives of all leading scientific Academies may be held for the purpose of discussing scientific matters calling for international coöperation, and by this means preparing the way for international action. The Council of the Royal Society regard this question as one of great importance, and I am to request you to bring it before your Academy, and to ask whether that body would be prepared to join such an organization if established, and to coöperate in arranging the details for inaugurating it upon a practical working basis.

I have the honor to be

Very faithfully yours,

(Signed) LISTER,

President, R. S.

THE PRESIDENT OF THE NATIONAL ACADEMY OF SCIENCES, WASHINGTON, D. C., U. S. A.

THE NATIONAL ACADEMY OF SCIENCES,
WASHINGTON, May 12, 1899.

SIR: I have the honor to acknowledge the receipt of your communication of April the 14th last asking me to bring before the National Academy of Sciences a plan to establish an organization under which formal and regular meetings of representatives of all leading scientific academies may be held for the purpose of discussing scientific matters calling for international coöperation and by this means preparing the way for international action.

There is no meeting of the National Academy of Sciences until the 14th of November next, but I will lay the matter at once before the Council of the Academy for consideration.

I cannot doubt that the subject will receive its warm approval and that the Academy, on the recommendation of the Council, will accept and cordially join in carrying out the plan proposed. I have the honor to be

Your obedient servant,

(Signed) WOLCOTT GIBBS,

President of the National Academy of Sciences.

THE PRESIDENT OF THE ROYAL SOCIETY,
LONDON, ENGLAND.

THE ROYAL SOCIETY,
BURLINGTON HOUSE, LONDON, W.,
May 31, 1899.

Sir: On the 17th November of last year the President of the Royal Society addressed a letter to the Academie des Sciences of Paris, the Reale Accademia dei Lincei of Rome, and the Academie Imperiale des Sciences of St. Petersburg, in reference to a proposal that the leading Academies should meet at intervals to discuss matters which might demand international cooperation; and a similar letter was subsequently addressed to the National Academy of Sciences of Washington.

The letter was written in consequence of what had taken place at a meeting of German Academies at Göttingen in June of that year, at which representatives of the Royal Society were present; and we have communicated to a meeting of the same Academies which has just been held at Munich the favorable replies which we have received from each of the Academies whom we had addressed.

We have now the pleasure to inform you that the invitation to a meeting at Wiesbaden, on October 9 and 10, which this letter accompanies, is a step towards carrying out the proposal in question, and we sincerely hope that your Academy will be able to take part in the meeting, which is intended to be a preliminary one for the purpose of discussing the mode in which such an Association of Academies can be best organized.

We are, sir,

Your obedient servants,

(Signed) M. FOSTER,
ARTHUR W. RÜCKER.

Secretaries, R. S.

THE PRESIDENT OF THE NATIONAL ACADEMY OF SCIENCES, Washington, D. C., U. S. A.

KÖNIGLICHE AKADEMIE DER
WISSENSCHAFTEN.
BERLIN, den 13, Juni, 1899.

Die Königlich Preussische Akademie der Wissenschaften in Berlin beehrt sich im Verfolg ihres am 1. ds. Mts. abgesandten Einladungsschreibens zu einer Conferenz in Wiesbaden am 9 und 10 October ds. Js. behufs Grundung einer internationalen Association gelehrter Gesellschaften anbei den von den Akademien in Berlin, Göttingen, Leipzig, München und Wien vorläufig vereinbarten Plan der Grundung ganz ergebenst zur Kenntniss zu bringen. Weitere Vorschläge über die Einzelheiten der Organization und Geschäftsführung, die als Vorlage zur Discussion auf der Wiesbaden Conferenz dienen sollen, wird unsere Akademie sich erlauben in kürzester Frist nachzusenden. Wir bitten aber uns schon jetst mittheilen zu wollen, ob die National Academy in Washington principiell geneigt ist an jenen Conferenz durch Absendung von Vertretern sich zu betheiligen und uns Namen und Adresse derselben bald gefälligst zur Verfügung zu stellen. DIELS,

Der vorsitzende Secretar.

AN DIE NATIONAL ACADEMY OF SCIENCES, WASHINGTON.

KÖNIGLICHE AKADEMIE DER WISSENSCHAFTEN.

BERLIN, den 24, Juli, 1899.

Die Königliche Akademie der Wissenschaften, welche die Delegirten Ihrer Akademie am 9. und 10. October auf der Conferenz in Wiesbaden zu begrüssen hofft, übersendet anbei 'Vorschläge zur Organization und Geschäftsführung,' die als Unterlage der Verhandlung dienen können. Genaueres über Versammlungsort und Stunde wird den Delegirten später direct mitgetheilt werden. Zu diesem Zweck ersucht die Akademie Namen und Adresse der Delegirten bis spätestens Ende September an das 'Bureau der Königlichen Akademie der Wissenschaften' Berlin N. W. Universitätsstrasse 8, gefälligst einsenden zu wollen.

Zum Schluss beehrt sich die Akademie mitzutheilen, das sie ihrerseits ihre Mitglieder die Herren Auwers, Virchow und Diels zur Conferenz delegirt hat. DIELS,

Der vorsitzende Secretar der Königlich Preussischen Akademie der Wissenschaften.

AN DIE NATIONAL ACADEMY OF SCIENCES, WASHINGTON, D. C., U. S. A.

KÖNIGLICHE AKADEMIE DER WISSENSCHAFTEN.

N. W. 7 Universitätsstrasse 8.

BERLIN, den Juni, 1899.

Die Königlich Preussische Akademie der Wissenschaften in Berlin beehrt sich im Auftrage der am 23. Mai ds. Js. in München versammelten deutschen Akademien und in Einverständniss mit der Royal Society, deren Regleitschreiben beigefügt ist, die National Academy, Washington, zum Zwecke der Gründung einer internationalen Association gelehrter Gesellschaften auf den 9. und 10. October ds. Js. nach Wiesbaden zu einer constituirenden, Conferenz einzuladen.

Diese Einladung ergeht gleichzeitig an die Königlichen Gesellschaften der Wissenschaften zu Göttingen und Leipzig, Königliche Akademie der Wissenschaften in München, Académie des Sciences in Paris, Kaiserliche Academie der Wissenschaften in St. Petersburg, Reale Accademia dei Lincei in Rom, National Academy in Washington, Kaiserliche Academie der Wissenschaften in Wien.

Der Zweck der Association ist, wissenschaftliche Unternehmungen, welche von der Gesammtheit der vereinigten Körperschaften oder von einer Gruppe derselben oder von einer einzelnen derselben in Angriff genommen oder empfohlen werden, zu unterstützen und sich über Einrichtungen zur Erleichterung des wissenschaftlichen Verkehrs zu verständigen. Jeder einzelnen Körperschaft soll die Entschliessung über die Theilnahme sowie über Mittel und Wege von Fall zu Fall vorbehalten sein.

Es wird Aufgabe der Wiesbaden Conferenz, sein, Organization und Geschäftsordnung dieser Association zu berathen und über etwaige Aufnahme anderer gelehrter Gesellschaften Beschluss zu fassen. Ein genaueres Programm wird binnen kurzem den eingeladenen Academien zugestellt werden.

Vorläufig wird aus den zunächst fur die Wiesbaden Conferenz geltenden Bestimmungen mitgetheilt, dass jede Academie eine beliebige, nach ihrem Ermessen zu bestimmende Anzahl von Vertretern entsendet, die Abstimmungen jedoch nach Academien stattfinden. Die Sprache der Verhandlungen ist frei. Die Protokolle werden deutsch, englisch und französisch geführt.

Es wird in Aussicht genommen auf diese constituirende Conferenz in Weisbaden die erste Arbeitsconferenz der Association im Jahre 1900, und zwar in Paris, folgen zu lassen.

Nach Eingang der in Aussicht gestellten Bestimmungen und Vorschläge bitten wir eine Erklärung über die Beschickung der Wiesbaden Conferenz unter Mittheilung der Namen der Delegirten an unser oben angegebenes Bureau gelangen zu lassen.

Diels,
Der vorsitzende Secretar.

PLAN FOR THE FOUNDATION OF AN INTERNATIONAL ASSOCIATION OF LEARNED SOCIETIES, SUBMITTED BY THE ACADEMIES AT BERLIN, GÖTTINGEN, LEIPZIG, MUNICH AND VIENNA.

1. The formation of an International Association of the larger learned Societies of the world is regarded as expedient and as likely to prove of service to the advancement of science.

2. The object of this Association is to support scientific enterprises undertaken or recommended by the united Societies in common, or by a group of the same, or by any individual Society, and, further, to make arrangements for facilitating international scientific intercourse. Each Society shall, as regards any particular undertaking, reserve to itself the right of deciding whether it will participate or not.

3. At the conference to be held at Wiesbaden the organization of the Association and its business details will be more fully discussed, deciding at the same time, whether periodical meetings say every three or five years, shall be held, or whether such meetings shall take place at irregular intervals, as occasion requires.

4. The resolutions of the Wiesbaden Conference will be submitted to the individual Societies for their approval and sanction. The Societies will then, by the end of the year 1899, definitely inform some central authority appointed by the Conference, whether they intend or not to join.

5. Each Society is free to withdraw from the Association at any time.

6. The Royal Academy of Sciences (Berlin), in conjunction with the Royal Society (London), has invited the following bodies (here arranged in alphabetical order) to attend the Wiesbaden Conference:

1. Königliche Gesellschaft der Wissenschaften at Göttingen.

2. Königliche Gesellschaft der Wissenschaften at Leipsic.

3. Königliche Akademie der Wissenschaften at Munich.

4. Académie des Sciences at Paris.

5. Académie Impériale des Sciences at St. Petersburg.

6. Reale Accademia dei Lincei at Rome.

7. Kaiserliche Akademie der Wissenschaften at Vienna.

8. National Academy at Washington.

7. The question of the eventual admission of other Societies will be discussed at the Wiesbaden meeting.

8. Each body will exercise its own judgment concerning the number of representatives to be sent to Wiesbaden. At the voting the representatives of each Society will have but a joint vote.

9. The language to be used at the Conference will be optional: the minutes will be drawn up in English, French and German.

10. The Royal Society proposes that the first official meeting of the Association be held in the year 1900, in Paris.

All communications referring to the Wiesbaden Conference are to be directed to the 'Bureau der Königlichen Akademie der Wissenschaften,' Berlin, N. W., Universitätsstrasse 8.

PLAN FOR THE ORGANIZATION OF AN INTERNATIONAL SCIENTIFIC ASSOCIATION PRESENTED BY SIR MICHAEL FOSTER AND DR. H. P. BOWDITCH.

1. The members of the National Academies mentioned in the 'plan for the foundation of an international association of learned societies' (Berlin, June, 1899), together with those of such other Academies as may be chosen by a majority vote of the Academies represented at the preliminary conference in Wiesbaden in October, 1899, shall constitute an International Scientific Association.

2. The first meeting of the Association shall be held in Paris in 1900, and its subsequent meetings shall be held at such times and places as may be then or thereafter determined.

3. By a two-thirds vote of the Association, each Academy voting as a unit, representative Academies of other nations may be admitted to membership in the Association.

4. The objects of the Association are :

(*a*) To promote and make preliminary preparations for work requiring international coöperation for its prosecution.

(*b*) To facilitate intercourse, both professional and social, between scientific men of all countries.

5. The governing body of the Association shall be an International Council composed of one representative from each constituent Academy.

6. The Council shall hold its first meeting at such time and place as may be determined at the meeting of the Association in 1900, and shall make rules for its own organization and guidance, including the transaction of business by correspondence.

7. For the purpose of considering and framing recommendations concerning scientific enquiries calling for international coöperation special International Committees shall, upon recommendation of one or more constituent Academies, be instituted either at a general meeting of the Association, or when necessary during the intervals between such meetings, by the International Council.

8. Such International Committee shall consist of delegates appointed by the constituent Academies with special reference to their qualification to deal with the questions under consideration.

9. The first meeting of such a Committee shall be called by the President of the International Association or by the President of the Council, and at this meeting each committee shall adopt rules for its own guidance.

10. Each International Committee shall make a report embodying such recommendations as it may think advisable, to the President of the International Council who shall transmit the same to the constituent Academies.

11. The President of the Council shall, however, have power, if he see fit, before transmitting such reports to the constituent Academies, to submit the same to the Council, and this body shall have power to refer back the report to the committee for further consideration.

12. For the transaction of business, the President of the Council shall be authorized to employ a secretary whose compensation, as well as other necessary office expenses, shall be provided for by contributions from the constituent Academies.

DELEGATES TO THE WIESBADEN CONFERENCE, OCTOBER 9 AND 10, 1899.

1. Königlich preussische Akademie der Wissenschaften, Berlin : Auwers Virchow, Diels.

2. Königliche Gesellschaft der Wissenschaften, Göttingen : Ehlers, Leo.

3. Königlich Sächsische Gesellschaft der Wissenschaften, Leipzig : Windisch, Wislicenus.

4. Royal Society, London : Sir M. Foster, Rücker, Armstrong, Schuster.

5. Königlich Bayerische Akademie der Wissenschaften, München : von Zittel, Bechmann, Dyck, von Sicherer.

6. Académie des Sciences, Paris: Darboux, Moissan.

7. Kaiserliche Akademie der Wissenschaften, St. Petersburg : Famintzine, Salemann.

8. National Academy of Sciences, Washington : Newcomb, Billings, Remsen, Bowditch, Bell.

9. Kaiserliche Akademie der Wissenschaften, Wien : von Hartel, Mussafia, von Lang, Lieben. Ersatzdelegirte : Gomperez, Toldt.

BLUE FOX TRAPPING ON THE PRIBILOF ISLANDS.

THE value of the Blue Fox, *Vulpes lagopus*, as a fur-bearing animal, has caused the establishment of various 'fox farms' or 'ranches,' not only on the islands of the northwest coast, and especially in the Aleutian chain, but even on some of the islands off the coast of Maine ; and it is naturally desirable to ascertain how these may be made to yield the best results. The problem of the 'fox farmer' is to obtain the greatest number of skins in a given season without so reducing the breeding animals as to lessen the catch for the succeeding year. Natural losses, due to starvation, may be prevented by feeding, but as foxes are naturally monogamous, it is evidently necessary to render them polygamous in order to render fox-raising a decided success, and this is the great desire of the trappers.

On the Pribilof Islands, in Bering Sea, the Blue Fox has been trapped continuously for a long series of years, but not until recently has any attempt been made to study these animals with the view of not only systematically feeding and trapping them, but of endeavoring to effect such changes in their environment as would tend to make them polygamous. This attempt has been made by Mr. James Judge, who has for several years been Treasury Agent on the island of St. George, who has taken much interest in the fur seal and fox question, and to whom the information contained in this article is entirely due. From its isolation, its hilly, rocky character, and from the vast numbers of birds which resort to it for a breeding place, this island is admirably suited for the abode of the fox, the great drawback being the lack of food during the winter. This lack of food not only acts directly on the foxes by starving them, but causes them to abandon the island and go out on the floe ice whenever this drifts down upon the island, as it often, or usually does in early spring. In summer the foxes feed upon birds and eggs and to some slight extent, upon dead seal pups and the placenta dropped from those recently born. The bodies of the seals on the killing grounds are eaten to some extent, but these bodies rapidly decay, and besides during the killing season the supply of other food is most abundant.

Since the advent of pelagic sealing the foxes have had an abundant, though brief, supply of food in the fall in the shape of the seal pups whose mothers have been taken at sea, and who have starved in consequence. In 1896 every starved pup was devoured by the foxes, so that no actual count of them could be made, but from an estimate made by comparison with the known facts on St. Paul Island, their number was probably considerably over 2000, while in previous years it was much greater. The foxes have fed to some extent on the Pribilof Lemming, *Lemnus nigripes*, and seem to have nearly exterminated the little creature, since but one specimen was seen in 1896–97. In winter the foxes eat anything that comes to hand, extraordinary as it may seem, subsisting to a considerable extent on sea urchins, *Strongylocentrotus drobachiensis*, which are gathered at low tide. Considerable grass is found in their stomachs in winter and some worms, which they scratch up on the killing grounds, as well as with a few tunicates and an occasional fish bone; but it may be said that in winter the foxes lead a precarious existence. Some not very energetic attempts have been made to introduce the Cottontail Rabbit on St. Paul Island, and the Cottontail and Jack Rabbit elsewhere, but so far without success; the proposed introduction of the Spermophile, *Spermophilus empetra*, which is found at Unalaska, would probably succeed better.

On the Aleutian Islands dried salmon has been used for feeding the foxes in winter, and on St. George the experiment was also tried of using cracklings and linseed meal. This latter was evidently not to the foxes' taste, but it was found that by mixing the meal with seal oil it was eagerly devoured. In 1897 Mr. Judge decided to use the carcasses of the fur seals taken for skins, but as the catch on the Island of St. George has of late years become so small that the bulk of the meat is eaten by the inhabitants, a number of bodies were salted and brought over from the neighboring island of St. Paul. Mr. Judge tried the experiment of putting down fresh carcasses in silos, as well as of salting them, and this plan has, with one exception, been entirely successful. The exception was when some seventy foxes effected an entrance into one of the pits, where they feasted to such an extent before being discovered, that a few died. The salted bodies were freshened by protracted soaking before being fed to the foxes. As the trapping season drew near these carcasses were placed at night in the vicinity of one of the sheds, near which it was proposed to set traps, and, starting with four bodies, the number was increased as found necessary, until no less than ten were consumed each night.

When all was ready trapping was begun, box traps being used, in order that the foxes taken might be examined to ascertain their sex, the dead falls formerly employed killing whatever entered, regardless of sex or condition. All females were turned loose after being marked by clipping a ring of fur from the tail, an exception being made when white foxes were caught, all of these being killed in the endeavor to produce a breed none of which should turn white in winter.

As the use of box traps proved to be somewhat slow, a small enclosure, or corral, was hastily constructed adjoining a large shed, and so arranged that the entrance could be readily closed by a man stationed within the building. This plan proved an immediate success, the foxes entering the enclosure without hesitation, so that from five to forty could be taken at one time. Having been shut in the corral the animals were driven through a small door cut in the side of the shed into a room where they were caught by means of forked sticks pressed over their necks, these being superseded by boards with a U-shaped opening in one end. The foxes were then passed, one at a time, through a small door into a second room, where they were received by a gang of men and examined as to sex. The females were all released, while the majority of the males were killed by breaking their necks, the intention being to leave one male to every three females. All foxes liberated were marked as previously noted, and this mark was repeated whenever an individual was captured more than once, with the result that by the end of the season some animals had lost most of the fur on their tails.

The possibility of rendering the foxes polygamous remains to be seen, and it will naturally take a series of careful observations extending over a number of years to definitely determine this point. At present it can only be said that the catch of the second season on St. George did not fall below that of the first, and some observations show that the male foxes will have intercourse with more than one female, while the bringing together of the animals that would, under natural conditions be widely scattered, is a most important factor in rendering them polygamous. The curious fact presents itself that in every instance save one, the number of males taken exceeded that of the females, even towards the close of the trapping season, but it is, of course, possible that this may be due to the attraction of the females for the males and not to any excess in the birthrate of the latter.

Mr. Judge's observations have made it clear that the foxes have no predilection for any particular locality, the question of food being the main factor in determining their distribution. This was proved by trapping at various parts of the island, the result being that comparatively few animals were taken save at the village, while those caught at one locality would subsequently be taken at another. Consequently by judicious baiting they can be readily enticed from all parts of the island to the vicinity of the village, where they can be taken by wholesale, in such manner that the total number of foxes on the island can be pretty nearly ascertained, as well as the proportions of the sexes. The blue foxes seem to lack the proverbial craft of the other species, for not only did they readily enter the pen, but, as shown, by the marks, they entered again and again, some individuals being captured no less than five times, while a few were taken twice in succession at intervals of about ten minutes. That the scent of man about the corral should not deter the foxes from entering is not surprising, since, except during the trapping season, they have no cause to fear him. Such precautions as that of taking the animals out in a boat so that they may be killed over water seem rather absurd, the more that when pressed by hunger they will even devour the skinned bodies of their own species. One piece of information desired, as to whether or not the foxes would wander off on the ice floes when they were being fed, has not yet been obtained because, curiously enough, during the two years that the experiment has been made the ice has not happened to touch St. George.

Incidentally Mr. Judge has made observations on the food, size and condition of foxes, and has shown that the pelt does not improve with age, as has commonly been stated, but that the yearlings and two-year-olds have the best fur. As for weight, the smallest fox weighed a little over eight pounds, the largest a trifle more than fourteen, the great majority weighing in the vicinity of ten pounds.

The outcome of these experiments will be awaited with much interest, and if by a little artificial selection and environment a naturally monogamous animal can be rendered polygamous, the supply of blue fox furs will be materially increased.

The table appended gives the results of the catch for the season of 1898–99, and the total number of animals must seem rather surprising to one familiar with the island.

It only remains to add that the greatest number taken in any one evening was 245, of which 61 were killed; the second best night's work was 211, and of these 57 were killed.

Foxes taken on St. George during the season of 1898–99:

Male Blue Foxes trapped and killed	334
Male Blue Foxes otherwise killed	34
White Foxes killed, males and females	18
Male Blue Foxes trapped and released	110
Female Blue Foxes trapped and released	389
Total	885

THE DEEP WELL AT WILMINGTON, N. C.

The deep well which is now being bored at Wilmington, N. C., is of especial interest to geologists: (1) That in reaching granite, as it does at about 1109 feet, it shows the absence at this point of formations between the upper Cretaceous and the old crystalline floor underlying the coastal plain deposits; (2) it shows the existence there of an unfortunately and unusually thick series of salt-water-bearing strata, from 350 to 1100 feet below the surface; (3) it may throw some light on the relations between the deposits of the sand hill regions (generally classed as Potomac) and the upper Cretaceous beds penetrated by this well.

The well is located on the bank of the northeast Cape Fear river, at Hilton Park, one mile north of Wilmington. The river border at this point exhibits two terraces; one only a few feet above tide water, extending back a distance of 30 or more feet from the river; and the other rising 30 to 40 feet higher, extending back for a considerable distance, and indeed representing the general surface of the region. The difference in elevation between these two terraces represents the thickness of the remnants of the Tertiary fossiliferous clays and limestone and the overlying recent sands. The lower terrace represents the upper surface of the Cretaceous; so that the well starts in the Cretaceous clays and sands, and continues in them to a depth of some 1109 feet. In these sands and clays there are occasional beds of shell-rock and calcareous sandstone varying in thickness from a few inches to 30 feet, and occasional thin beds of clay containing small nodules or concretions. The sands are mostly micaceous and are usually quite fine grained, with a prevailing gray color. From about 700 to 800 feet, their color is decidedly greenish. Below 950 feet these sands become coarser and are interbedded with occasional gravel deposits, but they continue fossiliferous to near the surface of the granite.

Waterbearing sands and gravels were penetrated at a number of points, notably at 380, 496, 520 and 574 feet; and at 1011 the largest flow, of nearly 400 gallons per minute, was encountered, with pressure estimated as sufficient to raise the column of water 80 feet above the surface. Unfortunately the water from each of these levels was highly brackish, and hence unfit for domestic use.

The fossil forms secured at different depths have been identified by Dr. T. W. Stanton, of the United States Geological Survey. The method used in sinking the well is the ordinary drill and sand pump; and, as might be expected, in some cases only fragments of shells were secured; but as the hole was of large diameter (12 inches near the surface, then 10 inches, and lower still, 8 inches) and the larger part of the matrix material quite soft, a minimum amount of drilling was needed; and many large fragments and many perfect forms were obtained.

Among the fossils secured from the upper 700 feet, classed as Ripley cretaceous, the following may be mentioned:

Cardium eufaulense Gabb, was found at 40 feet and 538–558 feet, and fragments of this or another Cardium were found also at 50, 485–490, 520–540 and 556–575 feet below the surface.

Anomia argentaria Morton, was also common, having been obtained at frequent intervals from 40 to 600 feet; and fragments of an *Anomia*, too small for specific classification, were also found 800 to 900 feet below the surface.

Exogyra costata Say, was abundant throughout the upper half of the section; and below 500 feet a varietal form of this species, approaching *Exogyra ponderosa* Roemer in surface feature, was found almost to the granite.

Ostrea tecticosta Gabb, was common from 230 to 650 feet; and *O. larva* Lamarck, from 250 to 330 feet; and fragments secured at 518 feet probably belonged to one of these species. *O. subspatulata* Lyell & Forbes, was found only between 332 and 380 feet. Throughout the entire section, however, were found numerous fragments of *Ostrea* too imperfect to serve for specific determinations. *Veleda lintea* Conrad, and *Aphrodina tippana* Conrad (?) were found only at 340 to 500 feet. *Baroda Carolinensis* Conrad, and *Cyprimeria depressa* Conrad, were found only between 332 and 380 feet; and fragments of *Pecten* were found at 40 to 50 feet.

Gryphaea vesicularis Lamarck, was found at 250 to 265, and 720 to 735 feet (?); and *Inoceramus cripsii* Mantell, at 575 to 585 feet and probably also at 500 to 518 feet. Unrecognized species of *Avicula* or *Gervillia* were obtained at 390 to 400 feet; *Corbula* at 492 feet; *Pectunculus* 520 to 540 feet, and *Lunatia* 520 to 590 feet; *Lithophagus* 540 to 560 feet.

Cassidulus subquadratus Conrad, was observed at 518 to 538 feet, and echinoid spines and fragments of the same or allied species were also found at 100 to 170 feet. Sharks teeth, fish vertebræ, fragments of turtle shell, lignite and pyrite were found at intervals in the section.

Below 720 feet, and down to the granite (1109 feet) *Ostrea cretacea* Morton, which in the Chattahoochee river section is confined to the Eutaw beds, is here quite common; and is accompanied at intervals by *Anomia Exogyra*, *Cardium* and *Serpula*, the specimens collected being in each case too fragmental to permit of specific determination. This lower 400 feet of the Wilmington section has been classed by Stanton as *Eutaw*; and it is possibly the seaward representative of the Potomac arkose sands and clays of the sand-hill region northwest of Fayetteville, should these sands and clays prove to represent the latest Potomac. It is more likely, however, either that the Potomac deposits were removed from this region prior to the Eutaw deposition, or else that the surface of these old crystalline rocks was above water level during Potomac time, and hence not covered with deposits.

Underground temperatures were not taken at intervals at different depths while the work was in progress, owing to the lack of suitable thermometers; but there are now three wells only three or four feet apart, one 1100, one 500 and one 100 feet deep. The temperatures at the bottom of each of these, as determined by the use of a Darton deep well thermometer, were found to be 79°, 72.50°, and 68.50°F. respectively, giving a descending increase in temperature of about 1°F. for each 100 feet, between 100 and 500 below the surface; and 1°F. for each 98 feet, between 500 feet and 1100 feet below the surface.

J. A. Holmes.

Chapel Hill, N. C.

GRANITES OF THE SIERRA COSTA MOUNTAINS IN CALIFORNIA.

The Sierra Costa mountains occupy mainly the northeastern and northcentral portions of Trinity county, in northwestern California. They are the loftiest and most scenic portion of the Klamath mountain system, an off-shoot of the Sierra Nevadas. They consist, in general, of highly metamorphic clastics and ancient igneous rocks, including a basement crystalline formation, a massive serpentine, and a series of micaceous, chloritic, graphitic and hornblendic schists. All these are pre-Carboniferous in age; they have been subjected to intense orographic disturbance, folded and faulted on a grand scale, and into the fissures have been injected various granitic and dioritic dike rocks. Of these, granite, in hugh batholites, is by far the most important and bulky.

Three principal types of granite are represented, and they present some interesting contrasts: hence this paper.

On the western side of the head-water portion of the south fork of the Salmon river in Siskiyou county, there is a huge white mountain of nearby bare granite—Mt. Courtney of the Cariboo range. It is a massive batholite of true granite, consisting of large individuals of quartz, white feldspar and dark brown biotite, *but little or no hornblende*. It is very coarse-grained, the three rock species being crystallized on a scale of one-fourth inch. The color is a very light gray, as a soda-feldspar is a predominant constituent.

The Courtney granite abounds in vein-like dikes of aplite, a much finer grained white granite, in which the biotite is in small foils and sparingly developed. The contrast between the massif of very coarse-grained granite and the included dikes of fine-grained aplite is strong. Evidently they both represent the same magma, but it seems that after the coarse granite mass had solidified in its upper portion, great fissures were formed in it and the aplite arose in them, solidifying to form the curious dikes of white granite. The former is coarse-grained, because, being in one great mass, it cooled slowly, and the latter is fine-grained, because, being in thin dikes widely scattered through an already solid rock, it cooled rapidly.

Near the contact between the Courtney granite and the hornblende schists on the east, both granite and schist are cut by dikes of a white muscovite granite, a kind of fine-grained pegmatite. This contains neither biotite nor hornblende, and is more resistant to weathering influences than the other granites of this area. These pegmatite dikes are cut by a transverse system of dikes of dark green diorite-porphyrite, which also occurs in the coarse-grained biotite granite of Mt. Courtney, as well as dikes of very fine-grained light greenish gray diabase.

On the east side of the head of south fork of Salmon river, about three-fourths of a mile distant from Mt. Courtney, there is another granite batholite but it is composed of an entirely different type of granite. It contains the ordinary quartz, feldspar and biotite, but in addition, *it abounds in well-formed crystals of dark green and black hornblende.* The feldspar being largely plagioclase, it is a quartz-mica diorite, although its general appearance in the field is distinctively that of a granite. In fact, it is the rock commonly designated, by students of the Sierra Nevada region, granodiorite. It is finer grained and a darker gray in color than the Courtney granite.

This massif of granodiorite is at least a mile in length and one-half mile in width. It is one of a series of such granite masses scattered through the Sierra Costa mountains eastward from Mt. Courtney, some of which are as much as three miles in width. They all contain the large constituent of hornblende, and are characterized by spots of darker color, like included boulders of diorite-porphyrite, but which are probably concretionary in origin.

It is difficult to comprehend how such great masses of granite could be injected into the stratigraphic series, displacing the strata for miles. Mt. Courtney is but one of a series of high granite peaks extending southwest from it and apparently consisting of the same great massif of coarse-grained biotite granite, which may be ten miles or more in width. The strata of serpentine and schist must have been forced apart and up into high mountain masses, of which even Mt. Thompson, altitude 9345 feet, is but an insignificant remnant.

Between Mt. Courtney and the massif of granodiorite about three-fourths of a mile east of it, there is a block of mica and hornblende schists wedged in between the two granite masses. This dips steeply eastward, away from the Courtney granite and toward the granodiorite. As it approaches the latter it becomes nearly vertical, but the strata are cut off by the granodiorite. The contact is finely exposed and shows no contact metamorphism. The dark green hornblende schists are absolutely unchanged to the very contact. Fragments of all sizes up to 100 cubic feet, of the hornblende schist are included in the granodiorite from the contact in places, 100 or more feet distant. Some portions of it are a veritable breccia of schist cemented by granodiorite.

Now, the edges of all fragments are sharp and the corners angular. Nowhere is there the least evidence of partial fusion of the schist material even along the edges, by the heat of the great mass of 'melted' granodiorite in which it had become included. If the latter was *very* hot, it appears evident that during the long time which such a great mass must have required in cooling, the hornblende and quartz, of the schist fragments must have partially fused. The failure of this to occur to even the slightest degree, implies, in my mind, that the granodiorite was not very highly heated—not nearly so much so as other dike rocks of the same region. Yet that it was in a highly liquid condition is proved by its injection into the finest cracks of the adjoining schist. In short, I believe there is here abundant evidence to demonstrate a perfect fusion without great heat, a sort of 'wet fusion,' we may suppose, due to the presence of heated alkaline waters. The fragments of hornblende schist were impervious to this water, the heat not sufficient to produce a 'dry fusion,' and hence the present phenomena, described above. As this locality may prove a very interesting one to students of igneous geology, I will give it as the vicinity of Lake Catrina, on the mountain ridge just east of the head of the south fork of Salmon river.

The age of all the granites of the Sierra

Costa mountains is practically the same. They belong to a period of orographic disturbance during which the intrusives were predominantly granitic in distinction from an earlier diabasic and a later dioritic period of igneous activity. This granitic period was post-Carboniferous and pre-Tertiary. To make a finer distinction, many of the granodiorite dikes can be demonstrated to have been formed after the Mariposa slates of late Jurassic age (which they cut), and before the Shasta-Chico shales and sandstones of late Cretaceous age (which lie upon their eroded surface).

An interesting problem yet to be worked out is the relation between the biotite granite of Mt. Courtney and the granodiorite of the mountain country to the eastward. Why two such strongly contrasted granites of apparently about the same age and mode of formation should occur in such close juxtaposition as the Courtney and Catrina batholites on opposite sides of the valley at the head of the south fork of Salmon river, is to me a puzzling problem and one well worth considerable study.

Oscar H. Hershey.

AMERICAN PSYCHOLOGICAL ASSOCIATION.

The eighth annual meeting of the Association was held at Yale University, December 27th–29th, in affiliation with the American Society of Naturalists. In point of numbers and activity the meeting was one of the most successful in the history of the Association. Professor John Dewey, of Chicago, the President of the Association, was present in the chair, and on the afternoon of Wednesday, the 27th, read his presidential address on 'Psychology and Social Practice,' in which he discussed the relation of psychology to education considered as a form of social practice with which psychology might be expected to have most immediate concern, and then generalized the results reached to draw certain conclusions regarding the general value of psychology as a method to be applied in social life. (The address will appear in full in the March number of the *Psychological Review.*)

Following the address a formal discussion on 'How should psychology be taught?' was opened by Professor Fullerton, of Pennsylvania, who laid particular stress upon the question of the adjustment of the relative claims of the so-called 'new' psychology or psychology of the laboratory and the 'old,' which depends largely upon introspective analysis. He emphasized the necessity of both aspects in a general course, as well as the danger of giving undue prominence to either, and particularly, in America, to the experimental, owing to the tendency to extreme specialization in the subject in this country. Professor Fullerton further discussed the attitude which the university should take toward advanced students in the light of their future work. Professor Jastrow, of Wisconsin, continued the discussion and urged the importance of what he termed a 'functional' psychology in teaching, having the student verify facts and principles from his own experience, so far as possible from his own daily mental processes. He showed further the great value which experimental experience has for the introspectionist and agreed with the former speaker in deploring the quasi-antagonism of the two sides, arguing that both experiment and introspection are necessary and that they are complementary and in no way antagonistic. Professor Aikins, of Western Reserve, followed with a statement of the results of his own experience in teaching the subject, and described his method of combining experiment and text-book with collateral conferences. Professor Judd, of New York, closed the formal part of the discussion by calling attention to the peculiar difficulties encountered by the student of psychology due to the nature of the subject matter, the difference between observation and interpretation, and his questioning of inferred facts owing to the indirect method of arriving at them. The speaker argued that the difficulty is best avoided by first studying the indirect modes of treating subjective experience, that is, by a study of the physical and physiological conditions of mental life, always keeping in view its relation to the final treatment of mental experience toward which it is aiming. The discussion was continued informally by a number of the members from the floor.

The general program was long and varied. On Wednesday morning Professor E. F. Buchner spoke on 'Volition as a scientific doctrine,' and Professor G. S. Fullerton on 'The criterion of sensation' continuing a discussion developed in a paper on 'The psychological standpoint,' read before a former meeting of the Association, which endeavored to show what is implied in the recognition of psychology as a natural science. This was followed by what proved to be one of the most interesting papers of the session, viz., 'A new arithmetical prodigy with demonstration' by Professors E. H. Lindsay and W. L. Bryan. The subject is a boy, nineteen years old, the son of a stone mason, who has attended school seven years, made a fair record in all his studies and is of good general intelligence. Since the age of three he has shown a passion for numbers and has developed extraordinary powers in calculation. Since November, 1899, he has been under investigation at Indiana University. This investigation has been general and thorough and is still being carried on. The principal results thus far are as follows: In scope and tenacity of memory and in rapidity he ranks among the best recorded cases. He is unique in the large number of methods which he has worked out, and in the fact that he explains how and when he arrived at these. His rapidity is found to depend upon the great number of number relations committed to memory and upon the reduction in the number of operations through short-cut methods. The boy was present and gave demonstrations of his powers on both Wednesday and Thursday mornings, which were followed with great interest.

Professor W. S. Monroe closed the first session with a paper on 'Moral perceptions of school children,' describing an experimental investigation.

On Thursday morning the Association divided into sections, one for experimental reports and one for papers of more purely philosophical scope. Owing to the length of the program this sectional division was continued up to the end of the meeting. The experimental section on Thursday was opened by Professor E. A. Kirkpatrick on 'Individual tests of school children.'

Dr. T. L. Bolton spoke on 'The Reliability of certain methods for measuring the degree of fatigue in school children,' criticising the method of Griesbach with the æsthesiometer and the application of the ergograph to determine the fatigue value of subjects of the school curriculum. The speaker described experiments of his own, and reached conclusions unfavorable to the methods named. Professor E. F. Buchner described in detail 'A new number form,' and Dr. Robert MacDougall followed with a paper on 'The time values of accented and unaccented elements in rhythm.' Professor Chas. H. Judd described 'A method of securing enlarged records of voice vibrations' on smoked paper by means of an arrangement of two diaphragms. Records made were exhibited, and a detailed analysis of a four-syllable word was reported. Dr. E. W. Scripture reported on 'Researches in experimental phonetics. Dr. Max Meyer spoke on 'Elements of a psychological theory of music,' criticising sharply the current theories and insisting particularly upon the necessity of the number 7 in a scientific theory of music.

Dr. A. H. Pierce closed the session with a paper 'Is there an independent auditory space?' The speaker argued for the affirmative, basing his conclusion upon the phenomena of 'intra-cranial localization' occurring when two fusing sounds are given simultaneously, one at each ear, the resultant reference to the interior of the head being a genuine auditory phenomenon and not a localization made by the aid of factors borrowed from the visual or tactual space fields.

In the meeting of the philosophical section, held simultaneously with the foregoing, papers were read as follows: Professor E. H. Griffin, 'The natural history point of view in psychology'; Professor J. H. Hyslop, 'Kant's doctrine of apperception and the use of the categories'; Professor William Caldwell, 'Pragmatism'; Professor J. A. Leighton, 'Metaphysical method'; Professor Alexander Meiklejohn, 'The concept of substance.'

On Thursday afternoon the psychologists adjourned to meet with the naturalists for their annual discussion, Professor Jastrow representing the Association.

At the meeting of the experimental section on Friday morning, the first paper was by Mr. Clark Wissler on 'Some experiments on motor diffusion.' Mr. Wissler reported experiments showing the time relation between the primary, voluntary contractions of finger muscles and the accompanying secondary, unintentional contractions of the other arm muscles, the latter being due to a diffusion of the motor discharge. Primary contractions are first in order of time and are followed by secondary contractions in an order corresponding to their distance anatomically from the muscle innervated. Further, training finger muscles trains other arm muscles and training biceps trains finger muscles. Secondary contractions also take place on opposite side of the body. He argued that transference of practice effect is simply the result of diffused nerve currents.

'The influence of special training in general ability' was the subject of a paper by Drs. E. L. Thorndike and R. S. Woodworth. Experiments were reported in which special abilities were studied as follows: (1) The speed and accuracy of making certain complex observations, *e. g.*, of picking out from a page of print all the verbs or all the words containing both *r* and *e*, etc., etc. (2) The recognition of weights, lengths and sizes. (3) Attention to and retention of names. (4) Discrimination of two complex objects shown successively. In each set of experiments, after training in some one line, the subject was tested for general improvement in the same field. As far as the research has gone, the experiments fail to detect any pronounced influence of special training on general ability except in so far as a person may acquire in a special line of work certain methods and ideals of accuracy and speed which may be of use inther lines.

Professor J. McK. Cattell read a paper 'On relations of time and space in vision.' Experiments were reported showing that a surface moving under a window in a screen appears larger than the window and that if the surface exhibit two colors successively, say green followed by red for $\frac{1}{20}$ sec. each, the observer sees not green followed by red, but the two colors side by side or variously intermingled, the arrangement varying with the observer, but making for perception a spatial continuum. On the other hand, if the line of sight moves over objects, say a row of books on a shelf, each retinal element is successively stimulated but the objects are seen simultaneously, side by side, without fusion, even though the intermittent stimulations be as frequent as 1000 per second.

Thus fusion and indeed all phenomena of color-vision seem to be cerebral rather than retinal.

Professor E. B. Delabarre spoke on 'Conditions affecting the judgment of the direction of lines.' In the judgment of the vertical, besides the factors usually recognized, the following are of especial importance: (1) Attention—fixation does not usually coincide with eye fixation; the latter wanders much though unconsciously, and causes supposedly fixated line to appear constantly changing in degree and direction of inclination; (2) muscle-strains in eye and head also influence the apparent inclination. These same influences affect also other judgments of direction as well as of length and distance. Certain conditions as of illumination, etc., produce definite strains and tendencies to fixation of particular kinds which furnish a fundamental explanation for many forms of geometrical optical illusions.

Professor E. C. Sanford reported briefly upon 'Recent studies in the Clark laboratory,' with the following titles: (1) 'The development in school children of the ability to reproduce rhythms'; (2) 'The rhythm of nursery rhymes'; (3) 'The mental properties of the white rat as tested with the maze.' The first and last of these are portions of more extended studies of the general topics of rhythm and comparative psychology, and all are expected to appear in the *American Journal of Psychology* during the coming year.

Professor Joseph Jastrow discussed 'Pending problems at the Wisconsin laboratory,' and demonstrated various pieces of apparatus, many of them connected with the study of problems in visual perception. The Wood pseudoscope and the reflecting stereoscope were exhibited and explained, and a device for simplifying the demonstration of retinal shadows was shown. The demonstration further included a brief account of experiments in progress on the power of distinguishing in a shadowless light between convex forms varying slightly and regularly in degree of convexity. The sorting apparatus (see *Psychological Review*, May, 1898), was exhibited in its perfected and portable form.

Dr. E. W. Scripture demonstrated several devices in use in the laboratory where this meeting was held, and after some informal contributions and discussion the section adjourned.

In the philosophical section papers were read as follows: 'On practical procedure in inference,' by Professor J. G. Hibben; 'Elements of consciousness,' by Professor Mary Whiton Calkins; 'Choice and nature,' by Dr. E. A. Singer, Jr.; 'Methodology and truth,' by Professor J. E. Creighton; 'The spiritual principle in T. H. Green's philosophy,' by Professor E. B. McGilvary; 'The relation between the moral order and the natural order of the universe,' by Dr. David Irons; 'The development of content in moral judgments,' by Miss Ellen Bliss Talbot; 'The relation of ethics to religion,' by Professor W. G. Everett; 'The contents of religious consciousness,' by Dr. J. H. Leuba; 'Causes of scepticism,' by Professor E. H. Sneath.

At the business meeting Professor Joseph Jastrow, of Wisconsin, was elected President for the ensuing year, and Professors Ladd, of Yale, and Bryan, of Indiana, members of the Council; Professors James and Ladd were elected delegates of the Association to the International Psychological Congress to be held in Paris in 1900, and the Council was empowered to call a meeting of the Association in June in connection with the American Association for the Advancement of Science which will meet at that time at Columbia University.

LIVINGSTON FARRAND,
Secretary.

COLUMBIA UNIVERSITY.

MEETINGS AT COLUMBUS, OHIO, AND NEW HAVEN, CONN., OF SECTION H, ANTHROPOLOGY, OF THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

The meeting at Columbus began with the installation of the chairman, Professor Thomas Wilson and the election of a secretary in place of Dr. G. Dorsey, resigned.

The report of the committee for the 'Study of the White Race in America' was presented by Professor Cattell; it was proposed to establish a station for making certain physical and mental measurements at the next meeting of the Association.

In a paper on 'New Anthropometric Methods' Professor Cattell showed some photographs taken with a centimeter netting close to the face; the method was said to be of special value in making permanent records of an indefinitely large number of measurements. Dr. Frank Russell, in a well-illustrated paper told of his measurements on the skeletons of the Labrador Eskimos and New England Indians. Professor W J McGee described the beginnings of mathematics.

The archæological side of anthropology was well represented. Professor G. Frederick Wright claimed that the separation between the Columbia and Trenton deposits was not so great as supposed by many; an account of observations supporting this claim was given in a paper on the 'Correlation of the Glacial Deltas in the Lower Part of the Delaware and Susquehanna Rivers.' Mr. Cresson's finding of a paleolithic implement in a deposit correlated to the Columbia deposit need not be received with incredulity, as "this would not imply an antiquity more than two or three thousand years greater than that which is implied in the genuineness of the Trenton deposit."

Dr. W. A. Phillips gave a richly illustrated paper on the 'Aboriginal Quarries and Shops at Mill Creek, Union County, Illinois.' A paper was read from Dr. Robert Steiner on a 'Prehistoric Settlement, Big Kiokee Creek, Columbia County, Georgia,' with an account of numerous finds. Dr. Charles Slocum brought forward evidence showing the existence of prehistoric man in the Maumee River Basin.

Dr. Steiner also sent a paper on 'Allan Stevenson's Trance.' Professor McGee read a paper on the 'Cherokee River Cult,' by James Mooney. An account of 'Instruction in Anthropology in Europe and America,' was given by Dr. G. G. MacCurdy. Charles K. Wead gave an account of the 'Natural Diatomic Scale.'

The psychological side of anthropology was represented in the report and paper by Professor Cattell above referred to.

A paper, illustrated by lantern diagrams, was given on the results of 'Researches in Experimental Phonetics,' wherein the curves of the sound-waves in certain vowels and diphthongs had been carefully measured. 'The Inadequacy of the Present Tests for Color-blindness' pointed out the fact that the wool-test, in spite of its universal use in American railways, was not adequate to eliminate color-blind persons from posts where that defect is dangerous; a new color-sense tester was exhibited. In a paper on 'Observations on After-images and Cerebral Light,' several new observations were given as to the results of displacing the eyeballs in the effect of retinal (cerebral) after-images, Purkinje's figures and the image of the yellow spot. In observations on the 'Economy of Sleep' various methods of lengthening sleep were discussed. These four papers were by Dr. E. W. Scripture.

The Columbus meeting was a pleasant and successful one. Over 300 persons were registered for the general Association. The attendance in Section H ran as high as a hundred. The plan was used of connecting all the sections by a telephone system, and of having in each room a blackboard with the titles of the papers being read in all the other sections ; a person attending one section would remain until the announcement of the occurrence of some paper which he wished to hear in another section. The excursions to the gas fields, the coal mines of Hocking Valley, to Ft. Ancient, etc., were specially interesting features provided with a generosity truly Ohioan. The success of the meeting was largely due to the activity of the local committee and its chairman, Professor Thomas.

Professor Amos W. Butler, of Indianapolis, was elected to be Chairman, and Dr. Frank Russell, of Cambridge, Mass., to be Secretary of Section H, at the next general meeting of the Association. This meeting will occur during the third week in June, 1900, in New York City. Dr. Russell kindly performed part of the duties of Secretary at the Christmas meeting.

The special winter meeting of this Section was held in New Haven, Conn., on December 27th to 29th.

At the opening of the meeting Professor Wilson spoke on the need of introducing the Bertillon system uniformly into the measurements of criminals, conscripts, etc., and avoiding the present confusion of two systems and no system. Professor J. McKeen Cattell spoke of the projected station for measuring the members of the American Association for the Advancement of Science, at the next meeting in New York. Dr. J. W. Seaver's account of the result of the measurements of the women in the Freshmen classes in the three colleges at Wellesley, Oberlin, and the University of Nebraska, created considerable comment.

Professor Joseph Jastrow's paper on the anthropology of the occult, suggested the fundamental factor of thought involved in the vagaries of mind of the astrologers, alchemists, mesmerists, faith-cures, and similar folk.

'The art of the Thompson Indians' was described and illustrated with blackboard sketches by Professor Franz Boas. The graphic art of this tribe differs widely from that of the natives along the coast: they employ simple motives, each of which has a symbolic meaning ; in some cases decorating extensive surfaces by repetition of the elements of the design. The following paper by R. B. Dixon upon 'Some basketry designs of the Maidu Indians of California,' gave an account of an art perhaps somewhat more advanced but illustrating the same principles of conventionalism and repetition. A paper upon a kindred topic, 'Symbolism of the Arapaho Indians,' by Dr. A. L. Kroeber closed the morning session.

At the opening of the afternoon meeting, Prof. Franz Boas presented the results of the investigations of Captain G. Comer among 'The Eskimos of Hudson Bay.' The natives of Southampton Island are of special interest to the anthropologist, owing to the fact that they have escaped thus far the contamination that inevitably results from contact with white 'civilization.' They are literally a Stone Age people. The paper upon the 'Archæology of the Thompson River Region,' read by Dr. Harlan Smith, was illustrated by a number of lantern views, showing the talus slopes and other localities where graves were examined, as well as the disposition of their contents, together with various artifacts of the peoples inhabiting the region prior to the arrival of the whites. John R. Swanton, in a paper upon the 'Morphology of the Chinook verb,' stated that the Chinook language exhibited many characteristics peculiar to itself that differentiated it from other American languages. Ales Hrdlička presented the results of his 'Observations on the Ute Indians,' which included an account of their arts and customs, and especially of their physical structure. He regards them as inferior in every way to the adjoining Navajos; considerable uniformity of physical type prevails throughout the various bands composing the tribe. Dr. George T. Stevens exhibited a number of pieces of apparatus for testing the vision, and spoke of 'The pose of the body as related to the type of the cranium and the directions of the planes of vision.' Dr. Stevens also exhibited a number of lantern views illustrating the abnormal poise of the head that results from the adoption of an incorrect plane of vision, which he believed to be in some measure due to the shape of the eye socket, represented in craniometry by the orbital index.

An exhibit of stereoscopic and triple-color slides was made by E. W. Scripture, who also took the occasion to give the first public demonstration of his method of producing anæsthesia by an alternating electric current of moderately high frequency and without drugs of any kind.

The morning session of Thursday opened with a paper by Vice-President Wilson, entitled 'Similarity of thought not necessarily evidence of similarity in culture,' in which he dwelt more particularly upon the evidence obtainable among the higher civilizations—the evidence from the more primitive cultures having been presented in his address at Columbus. Dr. Wilson's investigations lead him to the conclusion that striking similarity or identity of thoughts is extremely rare in literature. G. F. Wright exhibited a number of specimens from Ohio, one of which, a 'Flint core with supposed artificial chippings found in the undisturbed gravel of the Tuscarawas Valley, at Massillon, Ohio.' George H. Pepper read a paper entitled 'Mosaic objects from Pueblo Bonito' that described the ceremonial objects inlaid with jet and turquoise, which have been found among the ruins of the Chaco cañon by the expedition organized by Messrs. B. T. B. and F. E. Hyde and under Mr. Pepper's direction.

Dr. D. A. Sargent presented the results of an extended investigation of physical correlations among Harvard students, particularly with reference to the 'Relation of height, weight, and strength to the cephalic index'. The dolichocephalic men were shown to be taller, heavier and stronger than the brachycephalic. In the discussion it was pointed out that this was in a great measure due to the fact that within the group the tendency is always toward dolichocephaly in the taller individuals and, furthermore, that the environment of the descendants of the earlier immigrants of a dolichocephalic stock was much more favorable than that of the other group. Frank Russell presented a preliminary paper upon 'Some cranial anomalies.' His investigations were made upon a series of over sixteen hundred crania of the American race, the percentages of occurrence of the various anomalies were tabulated, and the results presented a statistical form. George G. MacCurdy exhibited a number of 'Iron figurines from Styria' and described the character and distribution of this curious survival of primitive superstition.

The short afternoon session of the Section was devoted to the paper presented jointly by F. W. Putnam and G. F. Wright upon 'A human bone from the Trenton Gravels.' This important discovery must effectually silence many of the opponents to the theory of the antiquity of man in the Delaware Valley. The bone was found on the first of December, 1899; it is a section of a human femur, showing traces of having been artificially worked. It was found in the stratified and undisturbed gravels seven feet below the surface, at the margin of a canal that is being cut through the plateau, at Trenton. Several lantern views of the bone and of the locality from which it came were shown. It was moved that a vote of thanks be tendered the gentlemen, the Duke of Loubat and Dr. F. E. Hyde, who have advanced the funds necessary for the maintenance of the explorations by Mr. Volk, at Trenton.

At the meeting with the Folk-Lore Society on Friday morning, Section H was called to order by Vice-President Wilson for a short session, during which the committee appointed at the Columbus meeting to consider the advisability of advocating the introduction of the science of anthropology into the curricula of the higher institutions of learning, made its report. The report is given below.

After the adjournment of the Folk-Lore Society, the Section again met to hear Dr. E. Solotaroff read a paper upon 'Comparative Psychology.'

The following report of Committee on Introduction of Anthropologic Teaching, W J McGee, Chairman, was presented:

TO THE CHAIRMAN OF THE SECTIONAL COMMITTEE AND MEMBERS OF SECTION H, A. A. A. S.:

Your Committee on the Introduction of Anthropologic Teaching having exchanged views, chiefly through correspondence, beg to submit a preliminary report, defining a policy and outlining a plan for further work which seem to them feasible.

1. Your Committee are strongly of opinion that anthropologic teaching should be introduced in educational institutions of higher grade as rapidly as practicable; and they are strongly of opinion also that the Anthropologic Section of the American Association for the Advancement of Science is the fittest organization of national character to undertake the introduction of such teaching.

2. Your Committee fully appreciate the difficulties in the way of introducing anthropology into established curricula, especially (*a*) the attendant cost to the institutions, (*b*) the lack of definite information concerning the aims and scope of the science. With the view of overcoming these difficulties, the Committee have been led to recommend a plan for acquainting educational institutions with the methods and purpose of anthropology at a minimum cost, with the expectation that the interest thereby developed may lead to adequate provision for the subject in later curricula. The adoption of the plan would involve personal sacrifice on the part of working anthropologists willing to contribute in time and thought, but would seem to give promise of general advancement in the science.

3. Your Committee recommend that anthropologists desirous of promoting anthropologic teaching in America unite in offering to deliver, before high grade universities and colleges in which anthropology is not now taught, lectures outlining the science, explaining its great interest and utility, and setting forth its adaptability for college teaching; such lectures to be, at the outset, gratuitous, save for suitable provision for traveling expenses.

4. Your Committee recommend that, for the purpose of carrying out this plan, they be continued and given power to act and add to their number.

Your Committee suggest that any unexpended balance of the appropriation by the Council of the A. A. A. S. for the incidental expenses of the New Haven meeting of the Section be allotted for the printing of a suitable circular to be issued to educational institutions of higher grade.

E. W. SCRIPTURE,
Secretary.

TWELFTH ANNUAL MEETING OF THE GEOLOGICAL SOCIETY OF AMERICA, WASHINGTON, DEC. 27–30TH.

II.

On reassembling Friday morning the first paper was the following:

STRATIGRAPHY OF THE POTTSVILLE SERIES IN KENTUCKY.

MARIUS R. CAMPBELL, Washington, D. C.

This paper treated of the areal distribution of the conglomerates of the Pottsville series along the western margin of the Appalachian coal field in Kentucky and Tennessee. Three distinct horizons of conglomerates were described which heretofore have been regarded as a single stratum. Attention is called to the unconformity at the base of the series, and the vertical expansion southward was illustrated by numerous sections measured along the margin of the field.

In discussion David White remarked his having mentioned to the Society that the relatively thin cross-section of the carboniferous in this region only represented a part of the thick eastern outcrops. The older eastern Pottsville is lacking. I. C. White remarked the harmony of the results with those attained in Pennsylvania, and that in the late seventies he had realized the complex nature of the Pottsville in Pennsylvania and Ohio. He commented on the thickening to the south. David White also remarked the trough to the south. W. M. Davis asked about the relations of the marine deposits with corresponding fossils, and the fragmental deposits with land plants. J. J. Stevenson remarked the relations of the Devonian and Carboniferous continent to the sea. The Devonian is thin to the south and thick to the north, whereas the Lower Carboniferous is thin on the north and thick to the south.

I. C. White, replying to W. M. Davis, said that the invertebrate fossils were marine and that the sandstones contained lime. M. R. Campbell said that the materials of the sediments are quartz and that they could not have been derived from lower-lying rocks, which are limestones. The quartz probably came from the Carolina mountains and therefore the water-body was large. Bailey Willis suggested that the Pottsville represented a coastal plain, which was successively transferred, worked over and concentrated.

RELATIVE AGES OF THE KANAWHA AND ALLEGHANY SERIES AS INDICATED BY THE FOSSIL PLANTS.

DAVID WHITE, Washington, D. C.

From an examination of the stratigraphic distribution of the fossil plants of the Kanawha Series in southern West Virginia, it appears that only the upper half of the Series contains the common and characteristic elements of the floras of the Alleghany Series of Northwestern Pennsylvania. The lower half carries a flora which seems distinctly older than any of the floras which occur above the lowest coal of the Alleghany Series.

The plants of the lower Kanawha Series are comparable to those of the Lower Coal Measures of the old World, whereas the plants of the Alleghany Series in Pennsylvania are referable to the Middle and Upper Coal Measures of the European basins.

The discussion of the correlation of the coal floras of the two regions was followed by a brief statement of the stratigraphic changes and conditions of deposition in the Virginian region, as indicated by the distribution of the fossil plants.

I. C. White stated that although the floras changed from Pennsylvania to the Kanawha, the coal seams and sandstones could be traced without a break, from hill to hill. He, therefore, maintained the physical identity of the seams, viz., the Upper Freeport and the Stockton; one of the Kittanings and the Peerless gas coal, etc. M. R. Campbell remarked the possible diagonaling of sandstone and shales, and the pinching out of some. J. J. Stevenson corroborated I. C. White's statements to the letter, and insisted that the difference was a botanical and not a stratigraphic one. H. S. Williams supported David White by analogies drawn from the Catskill problem. I. C. White, in reply, again described the continuity of the Upper Freeport with the Stockton. He also stated that the marine forms contradicted the plants; that an abundant marine fauna beneath the Eagle coal corresponded with that of the ferriferous limestone. H. S. Williams and then I. C. White spoke again, but it was evident that there was a deadlock between the paleobotanists and the field geologists. The difference was so pronounced that all the rest of the Society hoped the two Messrs. White would go together over the field from one end to the other and report at a later meeting.

NEWARK FORMATION OF THE POMPERAUG VALLEY, CONNECTICUT.

WILLIAM HERBERT HOBBS, Madison, Wis.

The Newark formation of the Pomperaug Valley rests unconformably upon and is entirely surrounded by Cambrian and pre-Cambrian gneisses. Its sedimentary beds consist mainly of material of other than local derivation, associated with which are sheets of basalt which were once poured out at the surface. Subsequent to their formation the rocks of the area were elevated, tilted to the southeastward at a low angle, and while in this inclined position depressed an amount not less than 2000 feet. This depression of the area was accomplished through an elaborate system of dislocations (gravity faults) involving hundreds of individual fault planes. Of these more than 200 have been mapped.

The fault planes as mapped are quite regularly spaced. The area is thus cut up into blocks of regular shape, and these blocks are in some cases found to be further subdivided by parallel faults of small displacement until the faulting passes ultimately into prismatic jointing. The directions of the fault planes, which have almost a vertical hade, bear N. 54½° E., N. 5½° W., N. 15° E., and N. 34° W., with less common faults in other directions. Wherever large displacements have resulted from faulting, they are found to be distributed over a number of parallel planes, so as to produce a regular step, or *rampart* structure.

The crystalline gneisses and schists surrounding the basin of the Pomperaug Valley have been deformed by faulting in the same manner as the Newark rocks themselves, thus making it clear that the theory of "lateral compression and differential faulting by accommodation of beds within the gneiss formation" cannot explain the faulting of the Newark formation, as has been claimed.

The peculiar block faulting discovered within the area has brought about a number of topographic forms of relief that have not before been recognized. The drainage of the entire area is found to conform to the deformation, so that both major and minor streams run in courses like eaves-gutters—broken lines with sharp elbows, the elements in the course corresponding in directions with the fault directions named above. The stream channels are generally square in cross section, with a level floor of nearly uniform width, similar to that of an artificial canal. The Pomperaug River, which drains the area, is an illustration of reversal of drainage brought about by the 'discovery' of an upfaulted block of gneiss in its bed. This has resulted in producing a new base level with the formation of a lake above it, which in a later stage has been drained by the pushing back of the divide of one of the principal tributaries, so as to capture the headwaters.

The broad terrane hypothesis regarding the extent of the Newark formation receives material support by this investigation, which shows that an irregular block of the Newark has been depressed below the level of the crystalline gneisses, so as to be by them protected from the abrasion of the ice of the glacial period. The system of faulting within the area furnishes many analogies with the cleavage of a crystal, the explanation of which is doubtless to be found in a probably strained condition of the area, due to the removal of support from below just previous to the time when the dislocations occurred.

The paper was illustrated by lantern slides.

It was followed without discussion by the next title, lunch however, intervening.

THE RIVER SYSTEM OF CONNECTICUT.

William Herbert Hobbs, Madison, Wis.

This paper is closely related to the preceding paper. The system of faults there observed was found to have determined the troughs in which flow the streams of the district.

The attempt has now been made to ascertain if the river system of the state indicates, throughout, the existence of similar troughs. A carefully prepared map based upon the recent topographical map of Connecticut by the U. S. Geological Survey, shows that all the master streams, together with their numerous tributaries, flow in troughs which correspond closely in direction with the fault directions of the Pomperaug Valley system, and with two additional closely related directions. The individual troughs can generally be followed into adjacent states, but no attempt has been made to determine their full extent. Some indication of a regularity in the spacing of the parallel troughs is afforded by the map.

The inference from these facts is that the entire area of the state of Connecticut (and presumably a considerably larger area) has been deformed by faulting in much the same manner as that of the Pomperaug Valley.

The paper was illustrated by a map and by lantern slides.

B. K. Emerson remarked the continuation of these faults to the north into Massachusetts. H. B. Kümmel inquired about the fault scarps and whether the cliffs shown in the views were the result of hard and soft beds. The author replied that they were eroded fault scarps. J. F. Kemp remarked the close correspondence of the phenomena in general with others in the Adirondacks and raised the question of the age of the northwest series as shown by the diversion of the Connecticut at Middletown. W. M. Davis discussed the general influence of faults in the early drainage, but thought that they would not be so influential in later time. He also remarked the possible efects of the mantle of Cretaceous strata which may have covered Connecticut. The effect of drift was cited in influencing the course of the rivers. He also felt that the faults were too rectilinear for natural cases. R. D. Salisbury raised the question of the possible connection of the direction of glacial striae with the rivers. Dr. Hobbs replied that there seemed no apparent one. H. W. Turner inquired whether the faults might not be so recent as to have had influence. Dr. Hobbs admitted its probability and cited the reversal of the Pomperaug by a block of gneiss. In general the paper excited the greatest interest, but the feeling seemed to be, that too many and closely related fault systems were carried over the state, and that too great emphasis was not to be placed on the correspondence of the rivers here and there with them.

JURASSIC ROCKS OF S. E. WYOMING.

Wilbur C. Knight, Laramie, Wyo.

This paper reviews the early history of the Jurassic investigations in Wyoming and gave the distribution of both the marine and fresh water beds in that portion lying east of the North Platte river and south of the Fremont and Elkhorn Railroad. Geological sections from several localities were discussed and reference was made to their fossilized remains. The Jurassic were distinguished from the Triassic. The question was raised as to the advisability of retaining the double term Jura-Trias, and its retention was opposed. The age of the fresh water beds was discussed. Some hints were then given as to the grouping of the Rocky Mountain Jurassic beds and the correlation of them with European.

S. F. Emmons remarked the interest of the work and the contrasts afforded by the Wyoming Jurassic with the Colorado beds. H. W. Turner spoke of the desirability of dropping the name Jura-Trias. W. H. Weed mentioned the parallelism with the Yellowstone Park Jurassic. Bailey Willis explained the early use of the term Jura-Trias, as coördinate with carboniferous and cretaceous, and that it would be split up into local names in the inevitable development of field observation.

THE CRETACEOUS AND TERTIARY SECTION BETWEEN CAPE FEAR AND FAYETTEVILLE, N. C.

J. A. HOLMES, Chapel Hill, N. C.

The speaker remarked the importance of the Hatteras uplift, which extends westward through the 'Sand Hill' region. An east and west section was exhibited passing through Wilmington, N. C., and it was shown that there was a great unconformity between the Cretaceous embracing the Eutaw (300′) and Ripley (800′) and the Tertiary. In the Tertiary very important erosion intervals were also shown at the close of the Eocene and Lafayette.

The paper was discussed by W. B. Clark, who remarked the relations of the strata to others to the north and especially the absence of the Potomac bed. N. H. Darton made a comparison between the section of the Wilmington well and the Norfolk well. G. B. Shattuck remarked the great oscillations of the Atlantic coast that were indicated by these sections. He cited thirteen known unconformities in the coastal plain. T. W. Stanton described the relations of the fossils brought up by the well-borings, to others from Florida. J. A. Holmes remarked the location of the hinge line of the oscillations and the plans now maturing for their measurement.

MESOZOIC STRATIGRAPHY OF BLACK HILLS OF SOUTH DAKOTA.

N. H. DARTON, Washington, D. C.

The Black Hills uplift brings to view the entire series of Mesozoic formations underlying the plains. These comprise Laramie, Fox Hills, Pierre, Niobrara, Benton, Dakota, Lower Cretaceous, Jurassic and Triassic formations. A detailed investigation has been made by the author of the beds from Jurassic to Pierre, and a large amount of detailed data obtained. Fossils have been discovered in the Jurassic beds comprising fish in the basal members, as announced last year, the southern extension of the marine fauna in the intermediate series and additional Dinosaur remains in the upper beds. The relation of the Dakota to the Lower Cretaceous formations were set forth, and an account was given of many newly-discovered features in the stratigraphy of the Benton and Niobrara deposits. In the Pierre shales there has been discovered a horizon of calcareous lenses of *Lucina occidentalis* giving rise to tepee buttes somewhat similar to those described by Gilbert in southeastern Colorado. There was exhibited a fragment of fossil fish found in the Triassic Red beds.

The paper was followed immediately by the next title.

TERTIARY SHORE LINES AND DEPOSITS IN THE BLACK HILLS.

N. H. Darton, U. S. Geol. Survey.

It has been found that the 'White River' (Oligocene), lake deposits of western South Dakota extend far up the flanks of the Black Hills to shore lines, which are beautifully exhibited in a portion of the region. The relations of these deposits throw important light on the physiographic development of the uplift at several of its stages.

The paper was beautifully illustrated by lantern slides, but as the hour was late and no discussion ensued.

In the evening the Society attended the reception and session of the Washington Academy of Sciences, at which Messrs. Merriam, Gannett, Gilbert and Dall described its general results. A collation followed, which afforded an admirable and welcome opportunity for social intercourse.

The last session of the meeting was called to order at 9:45 A. M., on Saturday, December 30th, and showed a rather slim attendance owing to the departure of many of the members.

The first paper was presented by G. O. Smith and W. C. Mendenhall, and was on the 'Tertiary Granite of the Northern Cascades, Washington.' This granite, which a later petrographical study may show to be a quartz monzonite or quartz diorite, extends over an area of at least 100 square miles. It is intrusive between the Tertiary sedimentaries, as shown by the numerous dikes penetrating the surrounding rocks. The sedimentary rocks are slates, sandstones and conglomerates, and show interesting contact phenomena. Much of the slate is metamorphosed into hornfels, and there is abundant development of such minerals as garnet, epidote and tourmaline along the contacts.

This intrusive mass is important in its relation to the age of the sedimentaries, and also in its relation to the basaltic flows farther south.

Professor W. M. Davis read the next paper on 'The Basin Deposits of the Rocky Mountain Region.'

The writer questioned the origin of the Tertiary lake beds of the West, and cited examples to prove his theory that many of them are fluviatile in origin. The sorting out and distribution of the sediments comprising the strata in these beds indicated stream deposition, and, therefore, basin deposits, rather than lake deposits, is the proper term for these beds. He classed deposits according to three modes of origin—'lacustrine,' 'fluviatile' and 'wash,' and argued for the fluviatile and occasionally the 'wash' origin of many of the so-called 'Tertiary lake beds' of the Rocky Mountains. His theory was opposed by Messrs. Weed, Emmons, Cross and Russell, all of whom upheld the lacustrine origin of most of these deposits.

Professor A. P. Coleman presented a short paper on 'Heronite and its Related Rocks.'

Professor Coleman exhibited some specimens of this new analcite rock, which occurs as a series of parallel dikes near Heron Bay, Lake Superior. The rock corresponds chemically to nepheline syenite, and he thought perhaps a petrographical study would show the presence of nepheline. The typical rock consists of analcite in which radiating bundles of feldspar and aegirine crystals are imbedded: while a variety occurs with more feldspar in fluidal arrangement, and a second variety where the feldspar is in the form of spheres, sometimes two inches in diameter.

The succeeding paper was by Dr. H. S. Washington on the 'Magnet Cove Laccolith.' Since the excellent work of the late Dr. J. Francis Williams on the Igneous Rocks of Arkansas, much more has become known through the work of Brögger, Lagorio and others about magmatic differentiation, and Dr. Washington's study of the Magnet Cove area leads him to believe that the soda-rich rock species abounding here are simply highly differentiated products of the same continuous flow, and not of three different periods of eruption, as was thought by Dr. Williams. Six analyses were shown which exhibited such a regular variation in the percentages of the various oxides, that the inference was strong towards magmatic differentiation. The central mass is a basic ijolite with low silica 36.51 per cent., and high calcium oxide and the surrounding more or less concentric masses increase their acidity giving, on the outer band a nepheline syenite with silica 53.38 per cent. and large increase in alkalies and low lime. These successive bands show abnormal arrangement.

Plagioclase is absent from the rocks. The abundant garnet is accounted for through the excess of lime, as shown in the analyses.

The time was too short to allow the speaker to dwell much upon the dikes, or upon the reason for calling the mass a laccolite.

The final paper was then presented by August F. Foerste on 'Further Studies on the History of the Cincinnati Anticline.' The theory held by former investigators that the age of this anticline is Lower Silurian and that the Upper Silurian strata were deposited during the gradual subsidence of the central mass, is untenable as shown by measurements of the adjacent strata. According to this theory the upper or last formed deposits would extend farther up the sides of the anticline, whereas careful measurements show that the lowest formations extend the greatest distance up the sides, and Mr. Foerste's theory is that these deposits at one time were continuous across the present anticline and on account of flexure and erosion now occupy the sides, thus indicating an age for the anticline later than the Upper Silurian.

Mr. Campbell agreed with the speaker that there was no evidence of Lower Silurian age for the anticline.

The following papers were then read by title by the President:

RECONNAISSANCE IN SOUTHEASTERN ARIZONA.

SCIENTIFIC BOOKS.

Electro-physiology. By W. Biedermann. Professor of Physiology in Jena. Translated by Frances A. Welby. Macmillan & Co. Vol. II., pp. 500.

Miss Welby's translation of the first volume of this well-known work was reviewed some time ago in these columns. It treated of the structure, contraction, and electrical stimulation of muscle, and of the electromotive phenomena of muscle, epithelium and glandular tissue. The second volume, comprising the structure, conductivity, excitability and electrical stimulation of nerve and the electromotive phenomena of nerve, electrical organ and vegetable cells, has now appeared.

When a physiologist of Professor Biedermann's eminence sums up the results of that department of the science which he has so brilliantly illustrated by the labors of a lifetime, and, knowing well how comparatively narrow will be the circle of his readers, lays his contribution at the feet of his fellow-workers, it may seem ungracious to criticise the gift. Yet we are bound to say, if criticism is not to abdicate its function, that praise must be tempered with censure in passing judgment on this book. That it is full of interesting and important observations, it is unnecessary to say. Even if the author had contented himself with an account of his own experiments this could not fail to be the case. But the treatment of the subject is not always so clear as might have been expected from so great a master. Unnecessary difficulties are placed in the way of the reader by the intricacies of a somewhat diffuse and ponderous style. The lack of proportion and perspective is conspicuous. The author, while doubtless himself well able to discriminate between the importance of weighty generalizations and that of petty experimental details, apparently makes little effort to help his reader to do so, and the student sometimes rises from the perusal with the feeling that he cannot see the wood for the trees.

The author naively admits, in the preface to his first volume, that he has not attempted to avoid partisanship in the treatment of certain topics which have given rise to the liveliest discussion and have separated electro-physiologists into warring camps. He has preferred, as he says, to present these thorny problems from the point of view of his master Hering, which happens also to be his own. The candor of this avowal almost disarms criticism. Yet we must say that although in a sketch such an attitude might be entirely excusable and even praiseworthy, it is to be doubted whether in a professedly exhaustive treatise like the present it is well to skate so lightly over the thin ice of controversy. For it is often impossible to thoroughly understand a question without a knowledge of the history of the disputes that have arisen in regard to it.

Like most of his countrymen, the author scarcely does justice to foreign and especially to

English-speaking physiologists. For instance, in speaking of the electrical variation produced when the retina is stimulated by light, the fundamental observations of Holmgren and of Dewar and McKendrick receive scant mention in comparison with the later, though doubtless valuable results of Kühne.

Of certain other sins of omission the candid critic has cause to complain. In a work of nearly 1000 large pages one would expect to find a highly special branch of physiology presented in an exhaustive way. Yet certain parts of the subject, and these not the least important, are barely sketched, while hundreds of pages are occupied with extraneous matter, or at least with matter which has no particular claim to be included. Why, for instance, should the structure of muscle and nerve, which is so much better treated in histological or anatomical works, cover over 60 pages, the discussion of the conductivity and excitability of nerve 60 more, and the alterations in form of the contracting muscle an additional hundred, while the secondary electromotive phenomena of nerve are dismissed in a bare half dozen pages?

Again, more than 50 pages are given up to the anatomy and histology of the electrical fishes, almost exactly as much space as is devoted to their electrical phenomena.

But although it is not free from faults, the book is a notable contribution to physiology, copious in its information, usually balanced in its judgments, and suggestive in the rare cases in which the author permits himself to speculate. The protest against Boruttau's extravagant hypothesis, which so completely identifies the negative variation with a physical katelectrotonus propagated in the form of a wave, seems to us entirely justified, and the arguments by which the protest is supported particularly cogent.

The translation is upon the whole well done, and better, we think, in the second volume than the first. Of course, as in all translations, there are a few cumbrous renderings which might be improved, and as in most, a few places where the meaning of the author is not expressed or is actually perverted. Occasionally a plural is inaccurately rendered by a singular. Not infrequently the otherwise commendable love of terseness on the part of the translator has led to the omission of qualifying words which it would have been better to translate. As a rule, however, the Anglo-Saxon pruning-knife has been advantageously employed to redress the diffuseness of Teutonic style. The division of the chapters by secondary headings, scarcely attempted in the original, is a great improvement. But it is to be regretted that the weightiest conclusions, expressed in German in spaced type, should not have been similarly indicated in the translation.

In a new edition, which we hope may soon be called for, such errors as the following ought not to remain uncorrected: 'Sewing needle' *for* 'Stricknadel' (p. 37); 'become paler in color' *for* 'einen blasseren Farbenton annehmen' (p. 37); 'inequalities' *for* 'Unvollständigkeit' (p. 38); '*near* the constrictions' *for* '*nebst* den Schnürringen' (p. 42); 'the *middle* part of the nerve rests upon the electrodes' *for* 'auf genau gleichen Elektroden ruht die *centrale* Nervenstrecke' (p. 62); 'itself' *for* 'daher' (p. 69); 'the strength of the peripheral stimulus is *the most* important factor in the diffusion of irradiation' *for* 'ist die Stärke des peripheren Reizes von *wesentlichem* Einfluss, etc.' (p. 70); 'the organ of reflexes, the automatic central structure of the brain and spinal cord' *for* 'die reflexübertragenden *und* automatischen Centralapparate, etc.,' (p. 78); 'built up' *for* 'geschlossen' (p. 87); 'exactly measurable' *for* 'genau abstufbaren' (p. 89); 'similarity' *for* 'Verschiedenheit' (p. 110) (doubtless a slip); 'differences of chemical *reaction*' for 'Verschiedenheit des Chemismus' (p. 111); 'the capacity of reaction, or alteration' *for* 'die Reactionsfähigkeit, beziehungsweise Veränderungen *derselben*' (p. 111); 'when the action of curara has *quite* worn off' *for* 'wenn die volle Wirkung des Curare * * * nachliess' (p. 112). On page 199 we read: "Against the cogency of these experiments there is good evidence to indicate that the electrical taste depends not upon electrolysis of the fluids in the mouth, but upon direct excitation of the taste-nerves." This is the direct opposite of the statement in the original. On page 109 curiosity is awakened by the mention of induction currents "applied directly to a fresh section on the ventral surface of the frog's spinal cord," but it is set at rest when we learn from the original that they were applied on the ventral surface of the spinal cord in the immediate neighborhood of a fresh cross-section. Again, some astonishment is caused by finding (on p. 51) that "one important fact that has hitherto been *overlooked* is the marked variation in calibre of medullated nerve-fibers." We ask ourselves whether it is possible that Biedermann did not know of the long series of investigations on this subject, beginning with those of Bidder and Volkmann half a century ago, and continued in our own day by Gaskell and his pupils and numerous other workers? On turning to the original, however, we find that Biedermann's innocent statement is that this important fact has not yet been '*mentioned*' (erwähnt) in his description. Similarly the at first sight somewhat mystifying contention of Grützner and Tigerstedt (p. 311) "that certain forms, perhaps, indeed, all opening twitches, produced by negative polarization currents are really closing twitches," becomes perfectly rational as a contention "dass gewisse Formen, ja vielleicht alle Oeffnungszuckungen durch den negativen Polarizationsstrom verursachte Schliessungszuckungen sind," which, being interpreted, means "that certain forms, indeed perhaps all opening twitches, are closing twitches produced by the negative polarization currents."

G. N. I. S.

Text-book of the Embryology of the Invertebrates. By Dr. E. Korschelt and Dr. K. Heider. Translated from the German by Matilda Bernard, revised and edited with additional notes by Martin F. Woodward. Vols. II. and III. London, Swan, Sonnenschein & Co.; New York, The Macmillan Co. 1899.

The admirable text-book of Invertebrate Embryology by Drs. Korschelt and Heider is scarcely in need of recommendation at this late day. If embryologists owe a debt of gratitude to Professor Mark and Dr. Woodworth for the translation of the first volume of the work, their obligations are even greater to those who have undertaken the more arduous task of translating the three remaining volumes. The two volumes just published contain the development of the Phoronidea, Bryoza, Brachiopoda, Crustacea and Insecta. Those volumes have been made of equal size by an adroit transposition of some of the chapters of the original text. One notes with pleasure the abolition of the oft recurring word 'fundamental' which the translators of the first volume used in the place of the German word 'Anlage.' As some embryologists have of late been much distressed about the proper translation of this term, it may be well to repeat Mr. Woodward's eminently sensible remarks on the subject. He says: "Exception, with which I concur, has already been taken to the use of this term [fundament], on the ground that the word fundament implies the solid basis or foundation upon which a structure rests or is built, where as an 'Anlage' is essentially a changing, growing structure, which, though at one time the foundation, when only the foundation exists, eventually gives rise to, or rather itself becomes transformed into, the fully formed organ.

"Having thus decided against the continued use of this term, I found myself face to face with the responsibility of selecting one of the numerous terms which have at one time and another been put forward as the English equivalent of 'Anlage,' at the same time time knowing full well that, whichever word was adopted, I should find a large number of biologists against me, as nearly every teacher of note has proposed at least one word which he believes to be the only correct rendering of 'Anlage.'

"Realizing, then, the impossibility of satisfying everyone, I thought it advisable to pass over all the numerous terms which have been recently suggested, none of which are really satisfactory, and to revert to that much abused word—rudiment. Most biologists will agree that the term rudiment, if it had not been misused by some of our most eminent zoologists, would undoubtedly be the best word by which we could render the German term 'Anlage.' Unfortunately, following the lead of Darwin and others, we have acquired the habit of applying the terms rudiment and rudimentary to certain structures present in the adult, which, in consequence of their small size and frequent loss of function, have retained a somewhat embryonic stamp, thus preserving the outward appearance of a rudiment, but losing its essential character, viz., its inherent tendency to further growth. These, then, are not rudiments, but arrested, reduced, vanishing, or vestigial structures, and should be spoken of as vestiges. Why, because Darwin unfortunately misapplied the word rudimentary, should we necessarily regard this misuse as hallowed, and ever after refuse to use the word in its common sense? To such an extent has this misuse of the word been carried that even encyclopædic dictionaries, after defining the word rudiment in such a manner as to prove that it is the very word we are seeking, as a rendering of the idea expressed by 'Anlage,' give us, under the technical use of the word, "In zoology, a part or organ, the development of which has been arrested (see Vestige)." It would require but little trouble on the part of teachers of biology to reinvest the word rudiment with its proper meaning. By carefully insisting on the use of the words vestigium and vestigial or their equivalents, for all abortive or reduced structures met with in the adult animal, and restricting the terms rudiment and rudimentary to all growing and developing tissues and organs, they could insure this result in a few years."

Ample compensation for the long delay necessitated by the change of translators and the size of the work is furnished in the additional matter in the form of foot-notes and bibliography, an addition without which a work on such a rapidly growing subject as invertebrate embryology would by this time be somewhat antiquated. Many of these foot-notes are valuable and suggestive, but others show a lack of perspective, pardonable, perhaps, in translators who cannot be expected to be familiar with all the bearings of the special matter they are rendering into English. An example of this kind is furnished by the undue importance attributed to Willey's paper on *Peripatus novæ-brittaniæ*. Important this paper undoubtedly is as a description of facts, but one may doubt whether Willey's speculations to the effect that *Peripatus* was originally a viviparous form and that species like *P. oviparus* are secondarily modified in their breeding habits, would have been given so much weight by the critical German authors as to lead them to alter their statement (p. 212) that "although the eggs of some species of *Peripatus* have little, or even no yolk, it is highly probable that they are to be traced back to eggs rich in yolk, like those of *P. novæ-zealandiæ*." Willey unfortunately involved the insect embryo in his speculations and here, too, the translators, without a vestige of critical caution, enthusiastically refer the student to the various homologies of the 'trophoblast.'

Such matters are of little importance, however, and are readily overlooked in the perusal of the flexible English rendering of the admirably lucid German text. The book is an invaluable addition to the collection of handbooks required in every zoological laboratory both in this country and in England.

WILLIAM MORTON WHEELER.

Bulletin of the United States Fish Commission, Vol. XVIII., 1898. By GEORGE M. BOWERS, Commissioner. Washington, Government Printing Office. Pp. 576. Plates 128.

The bound volume of the *Bulletin* for 1898 is the largest, and at the same time one of the most interesting, of the series of eighteen numbers which have appeared since 1881. In a prefatory note, Commissioner Bowers dwells upon the importance of the scientific work that has been carried on by those enjoying the privileges of the biological laboratory at Woods Hole, and his statement that "by affording facilities to those persons who may profit by the use of the material available at its various stations, the Commission not only aids in the general progress of science, but extends its own field of usefulness" will be heartily endorsed both by the many who have already profited by the liberality of the Commission, and by men of science generally.

The first article, beautifully illustrated, is by Commander Moser, now with Mr. Agassiz in the Pacific, and is a report on the operations of the *Albatross* during the summer, autumn, and early winter of 1897. It is a history of the 'Salmon and Salmon Fisheries of Alaska,' told in a straightforward way, and contains historical, geographical and biological data of present interest and of permanent value. Inasmuch as the output of salmon for a single year, 1897, was about 43,600,000 cans, one does not wonder that the streams of Alaska are becoming depleted. This depletion, already serious, is caused, not by over-fishing alone, but by 'barricading,' a process whereby the fish are actually prevented from ascending the streams to spawn, and are compelled to remain practically impounded in the lower waters, awaiting the pleasure of the packers. Although barricading is punishable by heavy fine and imprisonment, the laws are not enforced, and an industry now yielding $3,000,000 annually is threatened with ultimate extinction.

Dr. Hugh M. Smith, in charge of the scientific work of the Commission, and Mr. Barton A. Bean contribute a paper on 'The Fishes of the District of Columbia.' This and similar faunistic papers that the authors have published elsewhere have proved of great convenience to ichthyologists and local naturalists, and will be of no little assistance to students of geographical distribution. A second paper by Dr. Smith is on 'The Southern Spring Mackerel Fishery of the United States.' The paper gives an account of the history and importance of this fishery. It reviews the reasons for the prohibition of the fishery by Congress, in 1888; it gives an account of the fishery subsequent to the five years of closure, that is, since 1892; and considers certain questions that are suggested by the facts connected with this remarkable, and in many ways exceptional, action of Congress. It is to be regretted that the spring mackerel fishery, since the termination of the closed period, shows no improvement; the catches of the last seven seasons have not paid for the expense of equipping the vessels.

The article on 'The Mussel Fishery and Pearl-Button Industry of the Mississippi River,' by Dr. Smith, contains a description of the mussels used in button-making; a history of the mussel fishery, which has developed into an important industry during the present decade, nearly four thousand tons of shells having been collected by the fishermen of the Mississippi River in 1898; and a statistical review of the button industry, since the time of its establishment in Muscatine, Iowa, in 1891. The article concludes with certain timely recommendations, which, if early adopted by the States concerned, will prevent the destruction of the industry, now threatened by improvidence and avarice.

The eighth article, by Professor C. J. Herrick, is on the 'Peripheral Nervous System of the Bony Fishes.' It is based upon a study of the silverside, and emanates from the biological laboratory of Woods Hole. Since this paper was issued in the form of a reprint, Professor Herrick's magnificent monograph has appeared in the *Journal of Comparative Neurology*.

Another contribution from the government laboratory is made by Dr. Smith, in his 'Notice of a Filefish new to the Fauna of the United States.' A second capture of this filefish (*Alutera monoceros*) was reported in a recent number of SCIENCE. A third contribution from the laboratory is by the reviewer, and is a brief history of the discovery, disappearance, and final reappearance of the tilefish.

The concluding article is by Charles H. Stevenson, on the 'Preservation of Fishery Products for Food.' It covers more than two hundred pages, is amply illustrated, and is exhaustive in its treatment. The methods of retaining, curing, preserving, storing, packing, and shipping fishery products of the most diverse nature are thoroughly discussed by one who has evidently spared no pains to make his paper of real value.

H. C. BUMPUS.

BOOKS RECEIVED.

Scientific Papers. JOHN WILLIAM STRUTT, BARON RAYLEIGH. Cambridge University Press, 1899. Vol., I., 1869–1881. Pp. xiv + 562. $5.00.

The Kinetic Theory of Gases. OSKAR EMIL MEYER, translated from the second revised edition by ROBERT E. BAYNES. London, New York and Bombay, Longmans, Green & Co. 1899. Pp. xvi + 472.

An Introduction to Physical Chemistry. JAMES WALKER. London and New York, The Macmillan Company. 1899. Pp. x + 335. $2.50.

Outlines of Industrial Chemistry. FRANK HALL THORPE. New York and London, The Macmillan Company. 1899. New and revised edition. Pp. xvii + 541. $3.50.

SCIENTIFIC JOURNALS AND ARTICLES.

The Journal of Physical Chemistry, December, 1899. On 'Thermal and Dynamic Coefficients,' by J. E. Trevor; 'The Electrolytic Reduction of Potassium Chlorate,' by Adolph L. Voege. This is a quantitative study of the reduction of potassium chlorate under various considerations of density, current strength, poles of different metals, etc. Among the conclusions reached is the greater reduction in acid solutions than in alkaline, and the greater reduction with zinc poles than with those of cadmium or platinum; 'Note on the Preparation of Metallic Lithium,' by Louis Kahlenberg; metalic lithium can be obtained without difficulty by electrolysing a solution of lithium chlorid in pyridin, without the aid of a diaphragm. A carbon anode and iron cathode are used, fourteen volts difference of potential, and 0.2 to 0.3 ampere per 100 sq. cm. of cathode area. The metal is obtained in a dense, well-adhering, silver white coating, possessing all the well-known chemical and physical properties of metallic lithium.

A JOURNAL of Petrology is planned under the auspices of a committee appointed at the last International Congress of Geology. The journal is to have the scope of a Centralblatt, and it is proposed that contributions may be in English, French or German. Professor F. Becke, of the University of Vienna, is Chairman of the committee, and the American members are Professor J. P. Iddings of the University of Chicago, and Professor L. V. Pirsson of Yale University.

SOCIETIES AND ACADEMIES.

WISCONSIN ACADEMY OF SCIENCES, ARTS AND LETTERS.

THE thirtieth annual meeting of the Academy was held at Madison, December 28–30, 1899. The increasing number of meetings of national societies in Christmas week detracts somewhat from the attendance of members at the meetings of the Academy, but all five sessions of the present meeting were very satisfactory. The following list of papers were given and discussed:

'A study of the lead regions of Wisconsin, Illinois, and Iowa,' by Orin G. Libby.

'Household words—their etymology,' by James D. Butler.

'A problem in longevity,' by Charles H. Chandler.

'A new geometrical and analytical solution for determining the principal axes at any point of a rigid body,' by Charles S. Slichter.

'An elementary explanation of the probability curve,' by Charles S. Slichter.

'The ice ramparts formed along the shores of lakes Mendota and Monona during the winter of 1898–99,' by Ernest R. Buckley.

'The principles controlling the deposition of ores,' by Charles R. Van Hise.

'The nepheline syenite of the Wausau district,' by Samuel Weidman.

'Chlorine in natural waters—its accurate determination and significance,' by Erastus G. Smith.

'The action of light on certain nitroso compounds,' by Oswald Schreiner.

'The sour taste of acid salts and their electrolytic dissociation,' by Louis Kahlenberg.

'The historical development of chemical symbols from the times of alchemy to the present' (illustrated by lantern slides), by Oswald Schreiner.

'The absorption of the sun's energy by water,' by Edward A. Birge.

'Some of the undeveloped natural resources of Wisconsin: clays, road materials, and marls,' by Ernest R. Buckley.

'Account of some work done on the State survey,' by Dexter P. Nicholson.

'The work of the Wisconsin Geological and Natural History Survey,' Edward A. Birge.

Two additional papers were read by title: 'The Graphite Deposits of Central Wisconsin,' by G. E. Culver; 'On the Changes of Length of Substances in an Alternating Magnetic Field,' by W. M. Jolliffe.

At the one evening session a dinner was first given by the Madison members to the visiting members followed by a few speeches, including an eloquent plea by Professor Van Hise for the breadth of knowledge which the Academy aims to encourage. The company then adjourned to another room, open to the public, where the retiring President, Professor C. Dwight Marsh, of Ripon College, gave his address: The Plankton of Fresh Water Lakes. It was a well-written general discussion of the minute animal and vegetable life of our lakes, with some reference to economic features, and held the close attention of the audience to the end.

The Academy has now 225 members, and

there were elected at this meeting 18 active and two corresponding members. A new board of officers also were elected, for the term of three years, including Professor C. S. Slichter, University of Wisconsin, President; Professors Harriet B. Merrill, Milwaukee-Downer College, C. H. Chandler, Ripon College, E. G. Smith, Beloit College, Vice-Presidents; Professor F. C. Sharp, Secretary; Professor L. Kahlenberg, Librarian, both of the University of Wisconsin. The library of the Academy will be installed in the fine large building provided for the State Historical Society after the dedication of the building next May.

A. S. FLINT, *Secretary.*

MADISON, WIS., Jan. 1, 1900.

THE KANSAS ACADEMY OF SCIENCE.

THE thirty-second annual meeting of the Kansas Academy of Science was held at McPherson, on December 28–29th. This Academy is a coordinate branch of the State Board of Agriculture, and as such has rooms in the State House, and its Proceedings are printed by the State. The following papers were read at the meeting:

'On Apocynum cannabinum,' by L. E. Sayre.

'The first great roof,' by Charles H. Sternberg.

'Geology of the Glass Mountains of Western Oklahoma,' by Mark White.

'Silica cement mortars,' by William Tweedale.

'The home of the Kansas tiger beetle,' by Warren Knaus.

'An apparatus for determining the relative heating power of coal and gas,' by E. H. S. Bailey.

'Some interesting pyrite crystals,' by J. C. Cooper.

'The Leonid meteors of 1833 as observed by a native Kansan,' by J. R. Mead.

'An example of variation in the human cranium,' by H. J. Harnly.

'Additions to the published flora of Kansas,' by A. S. Hitchcock.

'The testing of paving bricks,' by F. O. Marvin.

'An historical list of Kansas mammals,' by D. E. Lantz.

'Stratigraphy of Eastern Kansas,' by G. I. Adams.

'On some Diatomacæ of Silver Lake and vicinity,' by George H. Curtis.

'Analysis of a magnesium water near Madison,' by F. W. Bushong.

'Collecting notes from Southwest Kansas,' by Warren Knaus.

'Notes on a trip through Western Wyoming,' by J. R. Mead.

'Comparison of the fauna of the Permian of England and America,' by J. W. Beede.

'A geological section of Lyon and Chase counties, along the Cottonwood River,' by Alva J. Smith.

'Harmonic forms,' by B. B. Smyth.

'Ecological areas in Florida flora,' by A. S. Hitchcock.

'Some mineral deposits in Central Missouri,' by S. Z. Sharp.

'The Corona of the sun,' by E. Miller.

Address of the retiring president on 'A theory of the cosmos,' by E. B. Knerr.

E. H. S. B.

WASHINGTON CHEMICAL SOCIETY.

THE regular meeting was held on December 14, 1899.

The first paper of the evening was read by Dr. Bigelow, and was entitled 'The Determination of Metals in Canned Goods,' by W. D. Bigelow and L. S. Munson.

After an examination of a number of the methods most commonly employed, the authors gave preference to a modification of Allen's method.

The entire contents of the can are thoroughly mixed, and 75 to 100 grams taken for analysis. Often it is found preferable to dry the entire sample, extract with petroleum ether, again dry and grind, to obtain a permanent sample. In this case only 25 grams are employed in the determination of metals.

In either case the sample taken is treated with 4 cc. of strong sulfuric acid, 2 cc. of nitric acid and 3 grams of magnesia. The whole is heated on a water bath until it becomes pasty. It is then ignited over a Bunsen burner or in a muffle furnace, until thoroughly charred, ground in a mortar, again ignited to complete combustion, nitric acid being added from time to time towards the close of the operation. The residue is then boiled for a half hour in about 40 cc. of 1–3 hydrochloric acid, almost neutralized with sodium hydroxid, precipitated with hydrogen sulfid and filtered. The precipitate is dried and thoroughly mixed with one gram each of sodium carbonate, potassium carbonate and sulfur, fused for one-half hour in a covered porcelain crucible, digested in water and filtered. The insoluble portion contains copper and lead. It is dissolved in nitric acid, and divided into two equal portions, in one of which the lead is precipitated as chromate and in the other copper is determined by titration with potassium cyanid. The filtrate from the fused sulfids is acidified with acetic acid, filtered and the precipitate thoroughly washed and transferred together with the filter paper to a solution of ferric chlorid, which is heated to the boiling point and titrated with potassium bichromate. Zinc is precipitated as sulfid in the filtrate from the original sulfid precipitate, after adding acetic acid and neutralizing the mineral acid with sodium hydroxid.

The second paper of the evening was read by Dr. Fireman and was entitled: 'The Action of Ammonium Chlorid upon Tetra- and Penta-Chlorides, Preliminary Communication,' by P. Fireman and E. G. Portner.

The last paper of the evening was read by Mr. J. D. Tinsley and was entitled, 'On the Estimation of the Water Soluble Constituents of Soils,' by J. D. Tinsley and F. K. Cameron.

Dr. Seaman spoke on the size of medicine droppers found in the market. He had found them variable, giving drops of different sizes. He showed that the size of the drop depends on the external diameter of the orifice and not on the thickness of the walls.

WM. H. KRUG,
Secretary.

DISCUSSION AND CORRESPONDENCE.

PREVENTION OF HAIL.

BUT little notice has been taken in the United States of the remarkable progress made in northern Italy in the establishment of stations for the protection against injury from hailstorms, by means of the *Wetterschiessen*—one of the old 'superstitions' which has come to honor again in our enlightened age. Shooting and ringing of church bells has for ages been popularly supposed to be efficacious against the effects of thunder-storms, especially of lightning. But the belief found no scientific support, and statistics seemed to prove that the rains supposed to follow the heavy cannonading of great battles are, like the weather changes following those of the moon, quite as much the exception as the rule. Now, however, the matter has taken the practical shape, in the form of stations located at intervals of not more than a kilometer apart in regions subject to hailstorms, and provided with a small cannon placed vertically and surmounted by a six-foot, narrow-conical trumpet, which transmits the vortex and concussion of a 2–3 ounce charge of black powder to the threatening cloud, preventing the formation of hail, and apparently also diminishing the electrical discharges. The idea originated with Burgomeister Moritz Stigel, of Styria, where after three years' experience complete exemption from hail-injury seems to have been secured, so that the inhabitants have abandoned hail insurance, finding the new method cheaper.

In the last semi-annual volume of Proceedings of the Academy of Georgifili, Florence, the subject is once more extensively discussed. A new style of breech-loading rapid-fire gun has been substituted for the original Stigel pattern, and 800 of these anti-hail stations have been and are being established in the region of Brescia, for the protection of vineyards. Small bombs with time fuses have been added to the equipment, and it is stated that the vortex, outlined by means of the dust, reaches the height of two kilometers, and that its low, whistling noise is heard from fourteen to seventeen seconds after the discharge.

E. W. HILGARD.

ELECTRICAL ANÆSTHESIA.

EDITOR OF SCIENCE: My attention has been called to an account in a New York paper of the method of producing anæsthesia by electricity, now being tried experimentally in the Yale Psychological Laboratory. Permit me to say that this account was entirely unauthorized. The demonstration of what had been accomplished was made informally at the recent meeting in New Haven of Section H of the American Association for the Advancement of Science, and no permission was given for any publication of the results. The last authorized statement in regard to the matter appeared in SCIENCE for March 10, 1899; unless there is some reason for the contrary, all future statements will appear first in the columns of SCIENCE.

E. W. SCRIPTURE.

NOTES ON INORGANIC CHEMISTRY.

In a recent number of the *Journal für Gasbeleuchtung* an account by M. van Breukeleveen and A. ter Horst is given, taken from *Het Gas*, of serious trouble from the formation of iron-carbonyl in water-gas mains. This Dutch works manufactures uncarburetted water-gas for use in Welsbach burners, and it is found that in a short time the mantel of the burner loses all its brilliancy owing to the deposition of a brown substance, which micro-chemical analysis proved to be iron. This proved to have been deposited from the iron-carbonyl formed, not in the process of manufacture of water-gas, but in its passage through the cold iron pipes, at ordinary pressure. The only practical remedy seems to be coating the interior of the pipes with tar. A similar deposit is often noticed on the lines used in the Drummond light, where instead of hydrogen, compressed water-gas or even coal gas in steel or wrought iron cylinder is used. Here the only remedy for the diminishing of the light consists in turning the lime quite often.

In the following number of the *Journal* Broockmann takes up the old problem of the gases contained in bituminous coal. At 100° E. von Meyer found a maximum of 238 cubic centimeters gas given off from 100 grams of coal, while Bedson found as high as 818 cc. The great variation in quantity as well as in composition is ascribed, in part at least, by Broockmann to the presence of more or less atmospheric air. He himself worked with a Sprengel vacuum which was kept with repeated warming for three days before the coal was heated, a temperature of 100° then being used. In this way a number of Westfalian coals gave from 7 to 150 cubic centimeters per hundred grams, an English coal 70 cc., a lignite from Habichtswald 50 cc. The gases obtained were generally chiefly methane with more or less carbon dioxid. Higher hydrocarbons, carbon monoxid, and oxygen were rarely present and then only in small quantities. One of the Westfalian coals gave little methane, more carbon dioxid, and over 60 per cent. of nitrogen. Two Oberschlesian coals gave a mixture of carbon dioxid and nitrogen, and the lignite gave 91 per cent. carbon dioxid and nine per cent. carbon monoxid. When heated with air in a closed tube to 160°–200° the oxygen of the air is completely absorbed, leaving only nitrogen with a very little carbon dioxid.

The precipitation of gold by iron pyrites is investigated by P. V. Gladkov in the *Berg- und Hüttenmannische Zeitung*. A solution of gold chlorid is completely precipitated by filtering through a layer of pyrites; if the pyrites carry copper, this and not iron replaces the gold in solution. The reduction takes place in pyrites which have been carefully washed by acid and hence is caused by the sulfid and not by any ferrous sulfate which might have been formed by weathering. The gold is precipitated not as sulfid, but as metallic gold, as is shown by the fact that it can be amalgamated with mercury. This study has considerable bearing on the treatment of pyrite ores of gold.

CURRENT NOTES ON PHYSIOGRAPHY.

THE CHATTANOOGA DISTRICT.

The 'Physiography of the Chattanooga district, in Tennessee, Georgia and Alabama' is elaborately discussed by C. W. Hayes (19 Ann. Rep., U. S. G. S., Pt. II., 1–54, 5 colored maps). The mountains of post-Carboniferous deformation were reduced in Cretaceous time to a broad peneplain (the Cumberland) with scattered or grouped monadnocks; 'unakas' being suggested as a name for grouped residuals. General uplift of the region allowed the development a less extensive peneplain (the Highland-Rim) probably in Eocene time; and a still later uplift permitted the excavation of the present valley floors in Neocene time. The peneplains are referred to subaerial instead of to marine denudation, after a critical review of their origin. Special consideration is given the development and adjustments of the drainage system; the chief streams first flowed westward into an interior sea; then southward along the troughs of Appalachian deformation; then westward again as a result of the shifting of divides by stream action chiefly in the first and second cycles of gradation. It is pointed out that the Tennessee may in the future be once more turned southward by the headward growth of the Coosa. Ridges of hard strata, produced by the dissection of an uplifted peneplain of monoclinal structure, are believed to retain their even crests while reduced toward the new baselevel, and hence should not alone be taken as indicating a peneplain. Differences of structure are recognized as controlling many local drainage adjustments, but broader modifications of drainage are believed to result from "the slight warping of the land service which appears to accompany all uplifts."

RIVER SPACING AND REGIONAL BEVELING.

A WELCOME continuation of the discussion on peneplanation begun by Tarr (*Amer. Geol.*, June, 1898) is found in articles by Shaler (Spacing of rivers with reference to hypothesis of baseleveling. *Bull. Geol. Soc. Amer.*, X., 1899, 263–276) and Tangier Smith (Some aspects of erosion in relation to the theory of the peneplain, *Univ. Cal.*; *Bull. Dept. Geol.*, II., 1899 155–178). The first article suggests that the often observed approach to uniformity of interval between adjacent valleys, and to uniformity in the slope of valley sides "tends to bring about a likeness in the height of the divides even where the original surface was of varied elevation"; and the so-called peneplains of the Appalachian region (such as those of the Chattanooga district, referred to above) are thought to be better accounted for in this way than by baseleveling; but the best preserved peneplain of this region, that of the Piedmont belt, is regarded as beyond explanation by river and atmospheric action, and is therefore by implication referred to a marine origin.

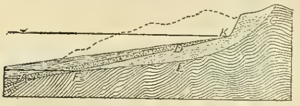
The second article deals more elaborately with the development of graded valley sides and with the correlations of summit height, side slope, and stream action in regions of mature dissection. The roughly equal spacing of the principal rivers of a topographic unit is said to 'follow as a necessary corollary' from the general principles thus deduced. Regions exhibiting a general uniformity of summit height, but so maturely dissected as no longer to preserve remnants of their initial uplands, are regarded as more probably explained by stream spacing and hill grading in the present cycle, than by peneplanation in a former cycle. The beveling of a region by the more rapid degradation of the hills near the coast than in the interior, as previously suggested by Tarr and here more fully stated, is held to give sufficient explanation of facts that have been referred by others to the unequal uplift or tilting of a peneplain. On the other hand, uplands that consist of truncated hills of accordant height, capped with residual soils and bearing old river gravels, are regarded as true uplifted peneplains.

As to beveling *versus* tilting, truly the degradation of hills must be a little faster near the coast than in the interior, but the excess does not account for the slanting descent of the New England upland southward to the shore of Long Island sound, or for the gradual decrease in height of the Cumberland penelain from Tennessee into Alabama.

AN ANCIENT PLAIN IN COLORADO.

W. O. CROSBY gives a detailed account of the remarkably smooth floor of crystalline rocks on which the Cambrian sandstones rest in the Rocky Mountain front range in Colorado. Although now tilted and more or less deformed, the floor is described as originally of very faint relief, with residual eminences only three or four feet high over areas of many square miles; but it may be noted that broad swells and troughs are not excluded by any direct evidence. Comparing this with other smooth sub-Cambrian floors in the United States, Crosby concludes that they are all parts of an extensive surface of planation (abrasion), produced during a period of slow subsidence, by marine attack on a region that "may very well have been reduced to a peneplain by prior subaerial erosion" (*Bull. Geol. Soc. Amer.* X., 1899, 141–164).

The occurrence of marine strata on a floor of firm, unweathered rock certainly points to marine abrasion before deposition began, but it may be urged that the prevailing absence of valleys in the even sub-Cambrian floor suggests the change of 'may very well have been' to 'must have been' in the preceding quotation. The broad floor was in any case the result of the destruction of an extensive pre-Cambrian highland or mountain region, for its rocks are of deformed structure or of deep-seated habit over large areas. During the long period of combined sub-aerial and marine attack upon the highland, large rivers must have cut down deep valleys, while sea waves abraded a plane around its litoral margin ; that is, the valley, *CEF*, would have been eroded, while the marginal plane, *AF*, was abraded. In the time needed to give *AF* a breadth of several miles, the main valley, *EF*, would be reduced to very



gentle slope. Under the supposition that the surface attacked by the encroaching sea was of such a relief that a considerable subsidence might occur during its submergence, the valley, *FE*, would in time be buried by the sediments, *ADK*. No buried valleys are known in the even sub-Cambrian floor. Their absence can be explained only under the supposition that the sea abraded the land to a greater depth than the valleys had been cut in it, and hence that but moderate subsidence occurred during abrasion. Under this limiting condition, extensive peneplanation must have occurred before great marine encroachment by abrasion could have been accomplished.

THE URAL MOUNTAINS.

THE excursion of the International Geological Congress to the Ural Mountains in 1897 gave Dr. F. P. Gulliver opportunity for reaching the following conclusions regarding the evolution of their existing form. A long period of sub-aerial planation, probably aided by marginal marine action, reduced the region to a lowland surmounted by a few monadnocks. The lowland was then arched by successive uplifts, the axes of greatest elevation being east of the middle of the range ; and benched valleys were eroded beneath the general upland level.

Approaching the range from the west, there is a gradual transition from the great Russian planes of nearly horizontal structure to the dissected peneplain of deformed structures. Approaching from the east, a part of the old mountain peneplain remains at moderate altitude adjoining the Siberian Tertiary plains ; unexplained lakes occur in this part of the peneplain, which is generally separated from the revived mountains on the west by an abrupt ascent, thought to be a weathered fault scarp (*Bull. Geol. Soc. Amer.*, X., 1899, 69–82).

W. M. DAVIS.

*NOTES ON TERRESTRIAL MAGNETISM.**

CAPTAIN DENHOLM FRASER, R.E., is at present engaged in making the necessary arrangements for inaugurating a magnetic survey of India and Burma.

CAPTAIN LYONS, R.E., in charge of Geological Survey of Egypt, has for some years been making magnetic observations during his journeys in various parts of Egypt. It is hoped that before long a systematic magnetic survey of Egypt can be undertaken.

TWO proposed sites for the Standard Magnetic Observatory in the vicinity of Washington have been examined during the past month by magnetic parties under Dr. Bauer's direction, in order to determine the most suitable place. One of these sites, situated twenty-two miles to the northwest of Washington, has revealed pronounced magnetic anomalies, while the other site, sixteen miles to the southeast of Washington, has thus far shown no abnormal values. The latter site appears to be also a favorable one as far as freedom from electric tramway influence is concerned.

THERE are at present four observatories at mining stations in Germany, at which the variations of the magnetic declination are being continuously recorded by photographic means, viz.:

1. Clausthal, Harz. This observatory has been in existence since the days of Gauss. It is provided with a Gaussian declinometer for eye-readings, and a more modern instrument for self-registering purposes. Copies of the daily records can be had upon application.
2. Beuthen, Upper Silesia.
3. Bochum, Westphalia.
4. Hermsdorf, bei Waldenburg.

The last three-named stations were started at

* From advanced sheets of *Terrestrial* Magnetism.

the suggestion of Professor Eschanhagen. They publish their declination traces regularly in the interests of the mining engineers.

WHILE residing in Cincinnati, Dr. Baur made magnetic observations about 100 meters west of an electric tramway (double trolley overhead system) running north and south. During the passage of a car, the declination needle was defected 1′—2′.

DR. L. A. BAUER returned to Washington on December 18th, having compared a set of the United States Coast and Geodetic Survey instruments with the standard instruments at the following observatories, viz.: Kew (before and after visiting the succeeding observatories), Potsdam, Pawlousk, and Parc St. Maur. He has also compared his dip circle with three earth-inductors of different construction. At Potsdam (Leonard Weter's inductor), at Pawlousk (Wild's portable inductor), and at Darmstadt (Karl Shering's inductor). The results will be published as soon as the various instruments of the Coast and Geodetic Survey have been intercompared, and when the comparisons at the Toronto Observatory have been made. Owing to the limited time at Dr. Bauer's disposal, it was necessary for him to restrict himself to the above-named observatories.

PROFESSOR E. LEYST, director of the Physico-Geographical Institute of the University of Moscow, includes in his department a systematic course on the theory and practice of measurements in terrestrial magnetism. His students are obliged to determine the magnetic elements, and to set up and operate a set of variation instruments and to determine the constants. The new institute, which will be a model building of its kind, is rapidly approaching completion. Professor Leyst has provided in this building for the installation of a set of variation instruments. The accompanying absolute observations will be made at a point outside of Moscow, far removed from any disturbing influence.

SCIENTIFIC NOTES AND NEWS.

THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

THE fifth Congress of American Physicians and Surgeons will be held at Washington on May 1st, 2d and 3rd, under the presidency of Professor Henry P. Bowditch. The following fourteen societies join in the triennial Congress:

The American Neurological Association.
The American Gynecological Society.
The American Dermatological Association.
The American Laryngological Association.
The American Surgical Association.
The American Climatological Association.
The Association of American Physicians.
The American Association of Genito-Urinary Surgeons.
The American Orthopedic Association.
The American Physiological Society.
The Association of American Anatomists.
The American Pediatric Society.
The American Ophthalmological Society.
The American Otological Society.

There will be two general sessions of the Congress. The subject at the first of these to be held on Tuesday afternoon, will be 'Bacteriology in Health and Disease,' and papers will be presented by Professor Theobald Smith, Dr. S. J. Meltzer, Professor Harold C. Ernst, Dr. Richard C. Cabot, Dr. Edward R. Baldwin, Professor William S. Thayer, Professor George Dock and Professor Simon Flexner. At the second session, on Wednesday afternoon, the program will be as follows:

'On Modern Therapeutics,' by Prof. William Osler, M.D., LL.D., of Baltimore, Md.

Essay, 'Sociological Status of the Physician,' by Dr. Clarence J. Blake, of Boston, Mass.

Poem 'The Evolution of the Physician,' by Dr. S. Weir Mitchell, M.D., LL.D., of Philadelphia, Pa.

Professor Bowditch will give his address as president on Wednesday evening, the subject being, 'The Medical School of the Future.' This will be followed by a reception and there will be a banquet on Thursday evening. The separate societies will hold their meetings on Tuesday and Wednesday mornings and on Thursday.

The Secretary of the Congress is Dr. W. H. Carmalt, New Haven, Conn.

THE SOCIETY OF AMERICAN BACTERIOLOGISTS.

AT the New Haven meeting of the American Naturalists during the Christmas holidays, a number of the leading bacteriologists of the country met, as previously announced in this Journal, for the purpose of forming a society of bacteriologists. As a result of the meeting there was organized a society which is the first in the country, and probably the first in the world, organized for the distinct purpose of studying and discussing bacteriological problems. The society will in general meet with the American Naturalists. The opening meeting was very auspicious, there being over thirty in attendance. The persons joining in the organization of the society included bacteriologists whose lines of study cover a wide range of subjects. Among them were those devoted to the study of pathology; others studying hygiene. Others again are engaged in the investigation of agricultural topics and yet others interested in the industrial problems of bacteriology. Some papers were also presented upon purely biological aspects of bacteria. The wide range of branches represented indicates the extent to which bacteriology has extended in the short years of its existence as a branch of science, and plainly points out the need of some organization to centralize the work and bring to a common point information of mutual interest.

In addition to the work of organization a program of papers was presented. A more complete account of these papers will appear in a later issue of this Journal.

The society elected the following officers for the coming year:

President, Professor W. T. Sedgwick, Mass. Institute of Technology; *Vice-President*, Professor A. C. Abbott, University of Pennsylvania; *Secretary* and *Treasurer*, Professor H. W. Conn, Wesleyan University; *Council*, Professor Theobald Smith, Professor Harold Ernst, Professor E. O. Jordan and Dr. E. A. de Schweinitz.

Bacteriologists desiring information concerning the society may apply to the secretary, Professor H. W. Conn, Middletown, Connecticut.

WASHINGTON ACADEMY OF SCIENCES.

The by-laws of the Academy were modified in May of last year by providing for a class of non-resident members. A committee representing each branch of science was appointed to consider the elegibility of men of science throughout the country for non-resident membership, and about one hundred members of this class have been elected. It is intended that the Washington Academy of Sciences shall become national in character, in so far as this does not conflict with the field of the National Academy of Sciences, and the American Association for the Advancement of Science. In view of the large number of men of science engaged in the work of the scientific bureaus of the Government and the frequent meetings of scientific societies at Washington, the City has especial claims to be regarded as the chief scientific center of America, and arrangements are contemplated for an annual scientific meeting under the auspices of the Washington Academy, which will be practically a congress of all the scientific men of the country.

At its annual meeting held January 17th, the Academy elected the following officers:

President, Hon. Chas. D. Walcott; *Vice-Presidents*, from the Anthropological Society, W J McGee; from the Biological Society, F. V. Coville; from the Chemical Society, Dr. H. N. Stokes; from the Columbia Historical Society, Hon. John A. Kasson; from the Entomological Society, Dr. Theo. N. Gill; from the Geological Society, G. K. Gilbert; from the Medical Society, Dr. S. C. Busey; from the National Geographic Society, Alexander Graham Bell; from the Philosophical Society, Dr. Geo. M. Sternberg; *Secretary*, Dr. Frank Baker; *Treasurer*, Bernard R. Green; *Managers, Class of 1903*, F. W. Clarke, Dr. C. Hart Merriam, Whitman Cross.

GENERAL.

The Geological Society of Great Britain will this year award its medals and funds as follows: The Wollaston Medal to Dr. G. K. Gilbert, of Washington; the Murchison Medal to Baron A. E. Nordenskiöld, of Stockholm; the Lyell Medal to Dr. J. E. Marr, of Cambridge; the Wollaston Fund to Mr. G. T. Prior; the Murchison Fund to Mr. A. Vaughan Jennings; the Lyell Fund to Miss G. L. Elles; and the Barlow-Jameson Fund to Mr. G. C. Crick and Professor T. T. Groom.

Mr. Percival Lowell of Boston, and Professor D. P. Todd of Amherst College, sailed for Europe on January 17th, and will proceed to North Africa to arrange for observations on the total eclipse of the sun occurring on May 28th. Mr. Lowell's telescope and camera are probably the best instruments hitherto used in such observations. Mr. A. E. Douglass will make simultaneous observations under Mr. Lowell's auspices in Georgia.

PRESIDENT DANIEL C. GILMAN has been granted a year's leave of absence by the trustees of the Johns Hopkins University. He will leave for Europe early in the spring.

PROFESSOR REGINALD A. FESSENDEN, of the electrical engineering department of the Western University of Pennsylvania, has resigned his chair to accept a position in the Signal Department of the United States Weather Bureau, at Washington.

THE Academy of Sciences at Belgium has elected as foreign members, Sir George Stokes, Sir John Murray, M. Moissan, M. Maupas and President Jordan.

THE Royal Astronomical Society of London has elected as foreign members, Professor George E. Hale, of Yerkes Observatory; Professor Robert Helmert, of Berlin University; Professor K. F. Küstner, of the Bonn Observatory; and Dr. Juan M. Thome, of the Argentine National Observatory.

DR. MANUEL ANTON, professor of anthropology at the University of Madrid and secretary of the Museum of Natural Sciences, has been appointed acting director to fill the vacancy caused by the death of Dr. Andres.

IT is gratifying to learn that the manuscript of the new edition of Coues' 'Key to North American Birds,' which has been largely rewritten and rearranged in conformity with the classification and nomenclature of the American Ornithologists' Union, was left by Dr. Coues in a finished condition, and will be published as soon as the new drawings, which are being made by Louis Agassiz Fuertes, are ready.

DR. JAMES MARTINEAU died in London on December 12th, in his ninety-fifth year. He began the study of civil engineering, but soon turned to theology and philosophy, and was appointed professor of philosophy in Manchester New College in 1840. He followed the College to London in 1857, and became its Principal in 1869. Dr. Martineau is well-known for his writings on theology and philosophy, of which one of the most important is 'Types of Ethical Theory,' published in 1885.

DR. WILLIAM A. HAMMOND died at Washington on January 5th. He was at one time Surgeon General of the United States and later Professor of Diseases of the Mind in Bellevue Medical College, New York.

THE *Auk* announces the death of two members of the Ornithologists' Union. Dr. D. Webster Prentiss, one of the founders, but since 1895 a corresponding member, died in Washington on November 19th. He was best known for his contributions to medicine, but published in conjunction with Dr. Coues a list of birds ascertained to inhabit the District of Columbia. Mr. W. W. Colburn, an associate member of the Union died in Springfield on October 17th last. He had been principal of the high schools at Manchester and Springfield, and did much to promote the study of natural history. He had published, in conjunction with Mr. R. O. Morris, a list of 203 species of wild birds observed in Forest Park, Springfield, Mass.

WE regret also to record the death on January 14th of Mr. W. T. Suffolk, treasurer of the Royal Microscopical Society of Great Britain.

MR. ANDREW CARNEGIE has given $50,000 for a library in East Orange, on condition that a site be provided and $5,000 contributed annually for its support. A similar offer has been made to the City of York, Pa., and $40,000 has been offered to the City of Covington, Ky., on the same conditions.

MR. M. L. DELAFIELD, Jr., of New York City, has qualified as the first patron of the Botanical Society of America by giving $250 to the Society.

A BILL has been introduced in the Assembly at Albany appropriating $30,000 to allow the State Engineer and Surveyor to continue to coöperate with the Director of the United States Geological Survey in making a topographic survey and map of the State of New York.

BY direction of the secretary of war, a board of medical officers, to consist of First Lieutenant Jere B. Clayton, assistant surgeon, U. S. A.; First Lieutenant, Richard P. Strong, assistant surgeon, U. S. A., and Acting Assistant Surgeon, Joseph J. Curry, U. S. A., has been appointed to meet at one of the general hospitals in or near Manila, for the purpose of studying tropical diseases in the Philippine Islands.

Dr. E. R. Hodge, pathologist at the United States Army Medical Museum, Washington, D.C., has left for Manila for the purpose of securing for that institution such pathological specimens as may result from active hostilities and the occupation of a tropical country.

We learn from the *Botanical Gazette* that the city of Philadelphia has acquired the dwelling and part of the grounds which belonged to James Logan (1674–1751), with Penn one of the founders of Pennsylvania, and a botanist of note, after whom *Logania*, the type of the Loganiaceæ, was named by Robert Brown. The property will be known as Stenton Park, the original name of the Logan estate, as there is already a Logan Square in the city.

Plans have now been submitted for the new building of the American Geographical Society, New York City, to be erected on West 81st street, opposite the American Museum of Natural History. The estimated cost of the building is $100,000. The façades will be of brick, granite, and terra cotta. An ornamental balcony of carved stone will have a place over the central entrance, with pilasters on either side. Two lamp-posts supporting globes will be put up at the entrance. Beneath the top tier of windows will be blocks of stone with the names of Columbus, Marco Polo, and Magellan. The first floor will contain the lecture hall, while the library will take up the second story.

At the first meeting of the Paris Academy of Medicine for the present year, the prizes to be awarded in 1900, 1901 and 1902 were announced. The prizes for the present year number 36, and vary in value from 300 to 6000 francs. They are, with a few exceptions, open to foreigners, but the manuscripts or printed works must be written in French or Latin. They must be presented not later than February 1st of each year.

The fiftieth anniversary of the foundation of the Paris Society of Biology was celebrated on December 24th. As part of the ceremonies, a commemorative tablet in honor of Claude Bernard, one of the founders of the Society and its second president, was unveiled in his old laboratory in the Collège de France. An address in honor of Bernard was made by M. d'Arsonval, his successor in the chair of medicine. Addresses commemorating the anniversary of the Society were made by the President, Professor Bouchard, and by the General Secretary, M. Gley. M. Leygues, the minister of public instruction, named as officers of the legion of honor, Professor Mathias Duval, M. Gréhaut, the chemist, and M. Capitan, secretary of the Society.

UNIVERSITY AND EDUCATIONAL NEWS.

A memorial has been presented to the Maryland House of Representatives asking for a continuation of the appropriation of $50,000 per annum for the Johns Hopkins University.

President Tucker, speaking before the Dartmouth Alumni Association of Boston, is reported to have said, that during the year six professors, six assistant professors and three instructors had been added to the faculty of Dartmouth College, and that the number of students had been increased by 50. The Wilder physical laboratory completed during the year was said to be the best equipped in New England. Gifts amounting to $150,000 had been received during the year in addition to $300,000 given by Amos Tuck. President Tucker wishes to collect $1,000,000 to celebrate the 100th anniversary of the graduation of Daniel Webster from Dartmouth College.

A committee has been appointed to enquire into the question of establishing a university college for North Staffordshire, England, and report in favor of trying to collect £20,000 for a building.

It is reported that President Ayres of the University of Cincinnati will recommend the discharge of the entire faculty of that institution at the end of the present college year, as a remedy for the troubles that have existed for a long time.

Professor F. A. C. Perrine has resigned from the chair of electrical engineering in Stanford University.

ELLIOTT COUES.

ELLIOTT COUES, the eminent ornithologist, died at Johns Hopkins Hospital, Baltimore, Md., December, 25, 1899, at the comparatively early age of 57 years. Dr. Coues was born in Portsmouth, N. H., September 9, 1842. In 1853 his father, Samuel Elliott Coues, removed with his family to Washington, D. C., where Dr. Coues was educated. He was fitted for college at the Jesuit Seminary, now known as Gonzaga College, and in 1857 entered what is now the Columbian University, taking his degree of A. B. in 1861, and his medical degree in 1863, and receiving later from the same institution the honorary degrees of M. A., and Ph.D. While yet a medical student he was enlisted as a medical cadet, and soon after graduation was appointed assistant surgeon in the United States Army, his first station being Fort Whipple, Arizona. Later he was assigned to Fort Macon, North Carolina, and afterwards to Fort McHenry, Baltimore. In 1873 he was ordered to Fort Randall, Dakota, and thence assigned as surgeon and naturalist to the United States Northern Boundary Commission, which surveyed the line of the forty-ninth parallel from the Lake of the Woods westward to the Rocky Mountains. The following six years were spent in Washington, the first two in the preparation of the scientific report of the Northern Boundary Survey, on the conclusion of which he was detailed as secretary and naturalist of the United States Geological and Geographical Survey of the Territories, under the late Dr. F. V. Hayden. In 1880 he was again ordered to Arizona, but the duties of a post-surgeon on the frontier were so incompatible with the prosecution of the scientific work he had then in hand that, failing to receive a more favorable assignment, he resigned his army commission in order to devote his whole attention to scientific pursuits. From 1881 till his death he resided in Washington, making, however, in recent years, several long journeys to the West and Southwest to aid his editorial researches in connection with the early exploration of our trans-Mississippi territory. For ten years, beginning with 1877, he filled the chair of Anatomy at the National Medical College in Washington.

Dr. Coues doubtless inherited from his father, who wrote several notable speculative works on physical science, his strong love for scientific research. His residence in Washington during his early years brought him into close contact with the late Professor Baird, of whom he was a pupil and ardent admirer, and who directed Coues's early ornithological efforts. His very first papers, published while he was still a youth of eighteen, took the form of technical monographs, and would have been creditable to a far more experienced hand. His 'Monograph of the *Tringeæ* of North America' and his 'Monograph of the Genus *Ægiothus*, with Descriptions of New Species,' both appeared in 1861, and in thoroughness of research and in method of presentation foreshadow the author's subsequent eminence in the ornithological field. These were quickly followed by his 'Synopsis of the North American Forms of *Colymbidæ* and *Podicipidæ*' (1862); 'Revision of the Gulls and Terns of North America' (1862); 'Critical Review of the *Procellariidæ*' (1864–1866), and his 'Monograph of the *Alcidæ*' (1868). In the summer of 1860 he made a trip to Labrador, which served as the basis of his notes on the 'Ornithology of Labrador' (1861), and later his residence at various army posts, both in the East and in the West, gave him a wide field experience, which he did not fail to utilize to the utmost.

During the twenty years from 1861 to 1881 he published 300 works and papers, mostly ornithological, and probably as many more between this latter date and the time of his death. Although his ornithological writings relate mainly to North American birds, they also include the science in its broadest sense. He also published a number of special monographs on various families of North American mammals. His contributions to the 'Century Dictionary,' representing about seven years of his best work, include some 40,000 entries which he either edited or contributed, he having editorial charge of the subjects, General Zoology, Biology, and Comparative Anatomy. Another important literary undertaking that absorbed the energies of his later years, also outside of ornithology, was the editing of the original Lewis and Clark 'Journals,' Pike's 'Account' of his journey to the Rocky Mountains, Fowler's 'Journal,' and Larpenteur's 'Personal Narrative.' These works are of the highest interest, relating as they do to the early exploration of western North America, and have been edited and annotated by Coues from the original documents, with a thoroughness and minuteness of detail that adds greatly to their value and interest.

Among Dr. Coues's more important special works may be mentioned the following: 'Key to North American Birds,' 1872, entirely rewritten and republished in 1884; 'Field Ornithology,' 1874; 'Birds of the Northwest,' 1874; 'Fur-bearing Animals,' 1877; 'Monographs of North American

Rodentia' (with J. A. Allen), 1877; 'Birds of the Colorado Valley,' 1878; 'Bibliography of Ornithology,' various installments, 1878–1880; 'New England Bird Life' (with W. A. Stearns), 1882; 'Dictionary and Check-List of North American Birds,' 1882. For four years he edited the publications of the Hayden Survey. Unfortunately only a small portion of his invaluable 'Bibliography of Ornithology' was ever published, but the published part has been of the greatest service to all workers on American birds, to which these portions mainly relate.

No work doubtless has had such a beneficent influence upon the progress of American ornithology as Coues's 'Key,' originally published in 1872, and republished in 1884 as a practically new work. During the last two years it has again been rewritten, and again transformed and brought down to date; we understand the manuscripts were left in such condition that the work will soon go to press, and will doubtless prove a lasting monument to the industry and skill of its gifted author.

Dr. Coues was not lacking in scientific honors. In 1877 he was elected a member of the National Academy of Sciences; he was also a member of all the more prominent American scientific societies, and of many foreign academies and societies. He was one of the founders of the American Ornithologists' Union, at one time its president, and always a member of its council and more important committees. He took a most earnest interest in its welfare and fame, and always viewed with satisfaction and pride his share in its organization and achievements, and his death will be held as a personal loss to his fellow members.

As I have said elsewhere (*Auk*, January, 1900, p. 91), Dr. Coues, as an all-around ornithologist, occupied a position of first-rank among the cultivators of this science. His influence upon the progress of technical ornithology in America is only second to that of Baird; as a popular writer on birds he was without a peer. His rare literary gifts rendered him a fluent and impressive speaker, and a writer of exceptional readability and originality of expression. His activity was prodigious and his capacity for work phenomenal. Though impulsive and at times somewhat erratic, he had many admirable traits, which none can so well appreciate as those who knew him most intimately.

J. A. ALLEN.

THE NEW DEPARTMENT OF VERTEBRATE PALEONTOLOGY OF THE CARNEGIE MUSEUM.

THE organization of this department in the Carnegie Museum during the past year has marked an important advance in the history of this young and growing institution. The unequaled facilities which the western portions of our country afford for the pursuit of this important branch of science have now come to be fully appreciated, and have within the past few years resulted in giving to this study an impetus which a few years ago was totally unknown.

The remarkable consecutiveness of this life record, together with its richness in vertebrate remains, especially in the Mesozoic and the Tertiary rocks, has permitted the gathering of collections of inestimable value when we consider what they contribute to the solution of some of the great problems in biology.

It has always seemed to me that our leading institutions have been unusually slow to recognize the value and importance of these collections, more especially when it is remembered that the greatest development of the science has taken place in this country and has formed such a conspicuous feature of American achievement in scientific investigation. The addition of a new member to the comparatively limited circle, capable of pursuing the subject in a comprehensive way is always a welcome event in science, and the unusually auspicious circumstances under which this, the youngest member of the fraternity, enters the list to compete for honors gives promise of substantial additions to our knowledge in this line of research.

In conformity with the special wishes of the founder of the Institute, Mr. Andrew Carnegie, the department was duly established during the early part of last year. The present force is as yet small, but this will in all probability be augmented from time to time, as occasion requires, and as the necessary space for the proper installation of the collections is secured.

The purpose of the department is the formation of a general collection illustrative of extinct vertebrate life from its earliest appearance up to the present period. This we hope to secure partly by purchase, but largely through expeditions into the various fossil-bearing horizons wherever such can be undertaken with reasonable promise of success.

The first expedition of this kind which was undertaken into the Jurassic formations of Wyoming has recently been completed, and the success attending this preliminary effort has been very gratifying indeed. The party consisted of the writer, in charge, Mr. W. H. Reed and Mr. Arthur Coggeshall, assistants, together with two laborers. A month was spent in the early part of the season prospecting in the vicinity of the 'Freeze Out' Range, on the western part of the great Laramie plain, Wyoming, where comparatively few specimens of interest were obtained. Early in July the Lower Sheep Creek Basin, in the northwestern corner of Albany county, was visited by the party, and a new field of unusual richness was discovered.

That which will prove of the greatest scientific interest and value in the collection, secured in this place, is the larger part of the skeleton of an herbivorous dinosaur, which was at first thought to belong to the genus *Diplodocus.* Of this almost the entire series of presacral vertebræ, the sacrum, and some fourteen or fifteen of the proximal caudals were secured. There are also a complete set of ribs, a scapula, coracoid, and sternum, a complete pelvic girdle lacking one ilium, and one complete femur; all in a most excellent state of preservation. The remainder of the limbs and the skull were not found, but there is much reason to believe that further excavation will bring them to light. No extended search was undertaken in view of the small force and the comparative lateness of the season when the other parts of the skeleton had been made ready for shipment.

This material, at the present writing, is but partially worked out and prepared for study and exhibition; but from the material already prepared it would appear that the genus which it represents is most nearly allied to, if not identical with that described by Professor Marsh from the Black Hills, South Dakota, under the name of *Barosaurus.* If it should transpire that it belongs to *Diplodocus*, which is somewhat doubtful, it will prove very acceptable in that it will supply us with nearly all the missing parts of the skeleton of this interesting group of dinosaurs. Should it, on the other hand, prove to be a species of *Barosaurus*, it will be yet still more interesting, since the genus is known from but a few fragments of caudal vertebræ, at least so far described.

One other specimen, which is certainly that of *Diplodocus*, was secured, in which a few characteristic bones of the skeleton are represented. Other specimens include considerable parts of the skeleton of *Brontosaurus*, among which is an exceptionally perfect hind limb, most beautifully preserved. This will enable us for the first time to fix definitely the organization of the hind foot of this rather abundant group of the Sauropodous dinosaurs. A description of this limb, with some excellent illustrations, will soon be published in the *American Journal of Science.* Still another specimen of great interest, from the underlying marine bed, includes a part of the skeleton with a well preserved skull, of the rare and curious toothless ichthyosaur (*Baptanodon*), originally described by the late Professor Marsh. Besides these, many other specimens were collected, the importance and scientific value of which cannot be fully determined until they are worked out and made ready for study.

The preparation of this material is under the skilful direction of Mr. Arthur Coggeshall, who was for some years connected with the American Museum of Natural History in New York, under the tutorship of that veteran *preparateur*, Mr. Adam Hermann. The material is being rapidly brought into shape for study and exhibition and by the time the new paleontological hall is ready for occupancy, we hope to have a good representation of Jurassic dinosaurs at least.

The department has been exceedingly fortunate of late in securing the services of Mr. O. A. Peterson, late of Princeton University, and previous to that of the American Museum and the U. S. Geological Survey, as chief assistant curator of the department. Mr. Peterson's skill and energy as a collector of vertebrate fossils, as well as his extensive knowledge of the fossil-bearing horizons of our western fields, are well known; he brings to bear a ripe experience (oftimes too lightly valued in the making of a paleontological collection) which cannot fail to be of the greatest advantage to the department in the acquisition of materials.

The work for the coming season will include, besides the continuance of the unfinished exploration in the Jurassic, two other horizons, which will necessitate practically three separate expeditions. From these sources it is hoped to augment the collections very considerably during the present year.

It has been stated recently in the columns of Science that the establishment of this department in the Carnegie Museum was due to the supposed discovery of a dinosaur of extraordinary proportions in Wyoming, in 1898, by Mr. Reed. While it may be true that the newspaper accounts published at the time may have hastened action in the matter, yet I know it to be a fact that ever since the founding of the Institute, Mr. Carnegie has had it in mind to bring together a first-class collection of vertebrate fossils as a part of the Museum exhibit. This is not at all surprising when it is known that he had an intimate personal acquaintance with both Professor Huxley and Professor Marsh, than whom, perhaps, no greater exponents of the subject could have been found, whose opinions and discoveries were calculated to make a more profound impression upon his mind relative to the importance and value of such collections for the general advancement of biological knowledge.

The broad basis upon which he has chosen to establish this undertaking, together with the liberal financial support which he grants to it, are sufficient evidences in themselves if no others could be had, that its inception was not due to a ridiculously exaggerated newspaper account of a bogus discovery, but to a well-conceived plan to carry into execution an important step in the growth of the Institute. It must be assumed that in thus establishing and liberally endowing a department of learning and scientific investigation of such a character, one whose results are destined to enter so deeply into the foundations of our future philosophy, he was not altogether unmindful of the fact that he would be erecting a monument to himself which will endure as long as science is cultivated. Let us hope that these expectations may be realized with the fullest measure of success.

J. L. WORTMAN,
Curator Dept. Vertebrate Pateontology.

AN INTERNATIONAL PLAN FOR THE FUTURE STUDY OF THE VARIATION OF LATITUDE.

UP to the present time the study of the variations of latitude, first observationally proved by Dr. Kustner, of Berlin, and developed by the investigations of Dr. Chandler, has been the result of the work of observers who have been specially interested in this subject.

The stations have not been well distributed for a thorough investigation of the interesting problem, because they have, as a rule, been centered near large observatories dealing with other astronomical matters, when they should be less in clusters, and spread over larger but uniform arcs of longitude.

The International Geodetic Association in the year 1898 formulated a plan which went into operation on January 1, 1900. The aim of the Association has been to put in service four stations, on the same parallel of latitude, and as well distributed around the earth as possible.

The four stations chosen, their latitude and the longitude east or west from Greenwich are as follows:

Mizusawa, Japan,	Lat.	39° 08′ 07″,	141°	E. L.
Carloforte, Italy	"	39° 08′ 12″,	9°	"
Gaithersburg, Md.	"	39° 08′ 10″,	77°	W. L.
Ukiah, Calif.	"	39° 08′ 12″,	123°	"

As one second of arc expresses about 100 feet for differences of distance near the above latitude, it will be seen that all the stations are within the limit of 500 feet of being on the same parallel line.

Professor Porter's observatory at Cincinnati, Ohio, happens to be very near the chosen latitude, and he will also engage in the work, having volunteered to do so.

It is also expected that a station will be established by the Russian government near a city called Tcharjui, and its longitude is 64° east. This observing station is especially important, for it places one between Mizusawa and Carloforte, and 187° from Ukiah.

In the past, many of the astronomers who have given for the use of the student the data necessary for a discussion of the variation of latitude, have made their observations conform to obtaining a correction to the Constant of Aberration from the same material.

The International Association intends that the series of observations which it has just inaugurated shall be made for the distinct purpose of deriving the latitude variation only.

Dr. Albrecht, of the Geodetic Service of Germany, has been greatly interested in formulating the plan of work, and has selected twelve groups, each containing eight pairs of stars. While this is in hand Professor Helmert has advised that each group contain two pairs of large zenith distance, as much as 60°.

Professor Doolittle, at Philadelphia, and Dr. Davis and Professor Rees, of New York, as well as other observers, have noticed in a night's work often an anomalous condition presenting itself in which every pair would clearly indicate an abnormal change of as much as a second of arc from previous and following night's results.

Professor Helmert's idea is to introduce these extra pairs to see if the cause for these marked changes would be more pronounced in those pairs of larger zenith distance.

All the stations are to use the zenith telescope. The instrument has been made by Wanschaff, and has an aperture of a little over four inches, and fifty-one inches focal length.

The method seems to be ideal, because each station will use identically the same reference points in the sky to determine the distance from each to the zenith, and whatever errors of absolute place each star or pair of stars may have, it cannot influence the result, for all use the same stars.

As they will all be reduced from the mean year to date of observation with the same constants, the only error that can in any way influence or mask the small variation of latitude is the proper motion that may obtain to each star, or each pair of stars. If any of the stars have large proper motion, the continued latitude derived from a pair thus affected will be either an increasing or decreasing latitude from that obtained from other pairs.

The completion of this plan in which the stations will be kept in operation, both by the German Geodetic Service, our own Coast Survey and the Russian government, places it upon a plane to sift to the utmost the hidden truths of the problem, and makes possible the determination by a long series of observations, if such is possible, the real value of the terms in the variation of latitude, and if they can be satisfied by any law of prediction as to the future movement of the pole.

GEO. A. HILL.

NAVAL OBSERVATORY,
WASHINGTON, D. C.

THE AMERICAN MORPHOLOGICAL SOCIETY.

THE American Morphological Society held its tenth annual meeting at New Haven, Conn., December 27 and 28, 1899. Among the items of business transacted may be noted the election of Dr. H. L. Bruner, Dr. G. A. Drew, Dr. C. R. Eastman, Dr. C. H. Eigenmann, Dr. J. Y. Graham, Dr. J. B. Johnston, Dr. F. C. Waite and Miss L. B. Wallace to membership in the Society; and the election of the following officers for the year 1900: *President*, T. H. Morgan; *Vice-President*, H. C. Bumpus; *Secretary-Treasurer*, J. S. Kingsley; *Members of Executive Committee*, F. R. Lillie, Jacob Reighard.

The following are abstracts of the papers read before the Society:

The homologies of the ear bones: J. S. KINGSLEY.

The chief points in the paper are the recognition of a distinct skeletal element between hyoid and mandibular arches which in the reptiles forms the extra-columella and in the mammals the manubrial portion of the malleus. In this element was recognized the branchial arch of a segment which has been pointed out in this region from the evidence of somites, neuromeres, cranial nerves, etc. The author maintained the identity of quadrate with incus, articular with the body (caput) of malleus and claimed that no matter what view one took of the homologies of the ossicles of the middle ear, they were forced to admit that the articulation of the lower jaw in the mammals was not homologous with the articulation of the mandible in the lower vertebrates. It was pointed out that the evidence for a reptilian ancestry of the mammals did not stand analysis, and that the origin of the group must be sought in primitive stegocephals.

The foramina of the scapula: J. S. KINGSLEY.

In embryo pigs 18 to 60 mm. long, the dorsal crest of the scapula presents four foramina through which pass dorsal nerves, arising from the second to fifth thoracic ganglia, and passing directly to the skin. These were regarded as possibly indicating that the scapula was made up of metameric parts, and it was pointed out that these results were in full accord with the recent studies of Bolk upon the muscles of the shoulder girdle. They might be interpreted as adverse to Gegenbaur's views as to the origin of the girdles.

On the development and morphology of the actual skeleton of vertebrates: CHARLES S. MINOT.

The author reported observations upon the embryos of man and other mammals, of the chick, and of fishes, which demonstrate the existence of a continuous cartilaginous perichordal rod, for which the term *chondrostyle* is proposed. The chondrostyle is probably the primitive stage, out of which the chondrocranium is developed where there are no myotomes, and out of which vertebral arches, and later vertebral bodies are developed, where the myotomes are persistent.

The arrangement of the mammary glands in litters of unborn pigs: G. H. PARKER and C. BULLARD.

An examination of 1000 litters of unborn pigs showed that the numbers in the litters varied from one to fifteen, the most usual number being six. As there were in all 5970 pigs the average number per litter was 5.97. Of the 5970 pigs examined, 2947 were females and 3023 males, or for every 1000 females there were about 1026 males. In the males the nipples varied from nine to eighteen, the most usual number being twelve and the average 12.434. In the females the nipples varied from eight to eighteen, the most usual number being twelve and the average 11.908. Litters of eight or less would always find ample milk accommodations. Litters larger than eight might be too numerous for the best milk accommodations, and as the number of nipples is not significantly larger in litters of large size than in those of small size, this lack of adjustment must at times be realized.

In abnormal carapace in the sculptured tortoise: G. H. PARKER.

An abnormal carapace of the common sculptured turtle showed at the posterior end of the series of marginal scutes, both right and left, two scutes in place of three, and in the middle of the carapace five bony segments in place of six. The variation in the bony segments is in mesodermic structures and lies anterior to the region of scute variation which is in ectodermic parts. As the ectoderm in tadpoles is known to migrate posteriorly over the mesoderm, it is possible that the same may occur in turtles and that the two regions of variation separated in the adult may have been in an earlier stage at the same transverse plane and induced by the same cause.

The trigemino-facial ganglionic complex of Gadus and Amiurus: C. JUDSON HERRICK.

The details of the composition of this complex as worked out by the author in Menidia, differ in some respects from those given by most other recent students of the cranial nerves of fishes. He accordingly, for purposes of control, worked out microscopically on Weigert sections the composition of the trigemino-facial complex in the codfish very fully and of the cat-fish somewhat less exhaustively. In both of these cases the results of this examination show very clearly that the plan of these nerves, and indeed of the peripheral nervous system as a whole, is fundamentally the same as in Menidia, with only unimportant variations in detail.

In Gadus and Amiurus the trigeminus is as in Menidia, save that the Gasserian ganglion is intra-cranial. In all of these types the facialis has three roots, motor, lateralis and communis, the latter being large in Gadus than in Menidia, and much larger still in Amiurus. In Gadus the geniculate or facial ganglion is crowded close to the Gasserian, yet clearly separable from it. It is intra-cranial and gives rise to the same nerves as in Menidia, except that it contributes nothing to the hyomandibular trunk and does contribute to the r. mandibularis V. The sympathetic system in this region is sharply separable from the cerebro-spinal, and there is no evidence that the facial ganglion is in process of transformation into a sympathetic ganglion. In Amiurus the geniculate is much larger and crowded still more closely up to the Gasserian. It can however be clearly shown that the r. lateralis accessorius in both Gadus and Amiurus is composed mainly of communis fibers and receives no fibers from the Gasserian ganglion.

From these results, and those of Strong, Kingsbury and others, it appears that the peripheral nervous system of Menidia presents us with a paradigm applicable in the broad view to the Ichthyopsida as a whole.

The Teleost gastrula and its modifications: F. B. SUMNER.

The prevailing view that the germ-ring alone furnishes the mesoderm and the entoderm must be revised, as well as the view that in teleosts, the periphery of the plastoderm represents the whole blastopore.

A specialized portion of the blastopore occurs at the posterior end of the embryonic shield a little anterior to the margin. In *Murœna* and probably some other fishes, this takes the form of an open invagination of the 'Deckschicht.' The cell thus invaginated becomes the gut hypoblast. The cavity persists for a while as that of Kupffer's vesicle. Thus Kupffer's original account, written in 1868, was very near the truth, although ignored or rejected by most of his successors.

In the cat-fish, trout and some others this blind sac is replaced by a solid ingrowth, such as Kowalewski described for the goldfish. Kupffer's vesicle is formed in this mass of cells which, in the trout, at least, probably furnishes the whole gut epithelium.

In the case of *Scorpœna* and probably many other pelagic fish eggs, this reduction has still further progressed, and we find at the posterior middle point of the blastoderm a small nodule of cells, causing a thickening of the 'Deckschicht.'

The present writer finds a condition in *Amia* quite comparable to that in *Murœna.* Although the egg of the former is holoblastic, its gastrula is very like that of the Teleosts and far different from that of the Amphibia. Dean has already pointed out in *Amia* the homologue of Kupffer's vesicle. The present writer also finds a rudimentary syncytium or periblast with giant nuclei.

On the embryology and phylogeny of Chimœra: BASHFORD DEAN.

The embryology of a chimæroid throws interesting light on the relations of this doubtful group. By this means the characteristic structures of Holocephali are shown to have arisen from distinctly Selachian conditions: the palato-quadrate in *Chimœra colliei* is thus early separate from the cranium: the frontal clasper is to be regarded as the homologue of a spine of first dorsal fin, which in ontogeny, owing to the precocious growth of the enormous eyes, shifts into its anterior position: the dental plates arise from separate anlagen, which in general are in the adult represented by the tritoral areas.

C. colliei spawns near Monterey, California, throughout the entire year, in deeper water (about 75 fathoms, sp. gr. 1.027, 55° F.). It deposits two eggs almost simultaneously. First cleavage about 26 hours after egg is deposited: early cleavages separated by intervals of from 3 to 6 hours. The young escapes from the egg-case in about 250 days. Polyspermy occurs. Blastula and gastrula distinctly shark-like. Early embryo with broad medullary folds. After closure of folds embryo differentiates as chimæroid. Eye increases enormously in size, altering the shape of the head, and accompanies ventral displacement and obliteration of the spiracle, and the fusion of the palato-quadrate with the cranium. Dermal margin of the hyoidean arch develops early and partly encloses the hinder gill slits. Long external gill-filaments (arising as in shark from the posterior margin of the gill bar) are now present. Tail becomes exceedingly long and attenuated. A highly specialized character is the mode of absorption of yolk material during late embryonic stages. The extra-embryonic blastoderm surrounds a lobe of the yolk: the latter comes to be reduced to independent lobes, and later to a milky fluid which is doubtless appropriated by the embryo by means of its external gills. These now present greatly dilated blood nodes, red in color. The late embryo lies in an opaque nutritive fluid, its relatively small and irregularly shaped yolk sac represents the small lobe early separated from the yolk.

On the occurrence of amphioxus at Bermuda: C. L. Bristol and F. W. Carpenter.

Amphioxus was first found in Bermuda by Professor G. Brown Goode in 1877, but no specimens have ever been studied from the lot then collected. In the season of 1897, the Second New York University Expedition dredged for them unsuccessfully, but in the next season specimens were secured by Professor Verrill in April, and again in June by the Third New York University Expedition at the locality described by Goode at the Flatts Bridge. In addition to this locality, the New York University party found them near Trunk Island in Harrington Sound. Specimens were sent to Professor E. A. Andrews, who reports that they promise to prove *Branchiostoma caribaeum.*

Budding in Cassiopea: R. P. Bigelow.

In the course of an extended study of the development of *Cassiopea xaymacana*, a rhizostomatous medusa obtained in Jamaica, the author found it possible to draw an interesting comparison between the process of budding and strobilization. The buds are formed one at a time on the lower part of the calyx of the scyphistoma. The bud is an evagination of the body wall consisting of three layers—ectoderm, mesoglœa, and endoderm; and in the mesoglœa are embedded four longitudinal muscles which are formed by outgrowths from the adjacent longitudinal muscles of the present.

In the formation of the strobila, the greater part of the scyphistoma is converted into the medusa disc, while the basal polyp is a comparatively small and simple appendage serving mainly for support. This, like the bud, consists of a simple sack with a wall of three layers—ectoderm, mesoglœa and endoderm, and in the mesoglœa there are four longitudinal muscles. Just before the separation of the medusa the basal polyp forms eight tentacles, and a ridge of ectoderm grows out in a circle surrounding the isthmus. When medusa is set free, this ridge enlarges to form a proboscis, more tentacles are developed, and very soon the basal polyp cannot be distinguished from an ordinary scyphistoma developed from a bud.

Before the bud is set free its proximal and distal ends become differentiated structurally, so that it is easy to distinguish them. Soon after becoming free the planula-like bud becomes attached to some solid support by its distal end, and the mouth is formed at the proximal end and becomes surrounded with a crown of tentacles, the orientation is just the opposite of what one would expect and corresponds with what Claus and Goette found to occur in Cotylorhiza.

So the bud and the basal polyp not only correspond in general structure, but in both it is the proximal end that forms the mouth and the distal end the foot. Their orientation is the same, and while attached to the calyx, their central axes meet as an acute angle, the distal ends being directed downward in both cases. Thus there is seen to be a striking analogy, if not homology, between bud and basal polyp. The formation of supernumerary tentacles and other structures is common in this species, so it may be possible to regard the bud as a supernumerary and precociously developed basal polyp.

Notes on the anatomy of Acmœa testudinalis, Müller: M. A. Wilcox.

The following points were made:

1. There is probable, though not conclusive evidence in favor of a winter migration to deeper water.

2. The inner face of the mantle is uniformly clothed with cilia borne, not continuously, but in patches some 20–30 μ apart.

3. Subepidermal glands are situated at the mantle margin. Unlike those described by Haller in a similar position, they are unicellular. Whether they contribute to the formation of the shell is uncertain.

4. The inner face of the mantle also bears subepidermal glands which are scattered and are probably unicellular mucous glands.

5. Animals killed by agents which produce strong contraction, exhibit folds of the mantle which lie parallel to the foot and contain blood spaces. These seem entirely similar to those described by Haller in *Lottia* (*acmœa*) *punctata* but in *A. testudinalis* are artefacts.

6. Both mantle tentacles and those borne on the head are richly provided with sense cells of Flemming.

7. The cephalic tentacles have each a large axial cavity which communicates with the cavity of the head. The wall surrounding the tentacular cavity consists of connective tissue in which longitudinal muscle fibres are imbedded and the tentacle, therefore, is intermediate between the ordinary solid prosobranch tentacle and the invaginable tentacle of the stylommatophora.

8. The chief nephridium closely resembles that of Patella, except that the portion which lies on the left side in *A. testudinalis* extends forward to the pericardium and probably communicates with it. The greater portion of this nephridium corresponds to what Haller describes as part of a coelom.

Locomotion in Solenomya and its relatives. G. A. Drew.

These forms burrow rapidly in mud or sand. The extremity of the foot is provided with two muscular flaps that may lie side by side or be spread apart. When the flaps lie side by side the extremity of the foot is wedge shaped, and the foot can easily be thrust into mud or sand. When the flaps are spread apart they form a very effective anchor. With the foot thrust into the mud and the flaps spread, a contraction of the retractor foot-muscles results in drawing the shell into the mud up to the position of the spread flaps. From this position another thrust can be made.

Beside burrowing, Solenomya swims quite rapidly. The thick elastic cuticle extends past the calcareous portion of the shell, along its ventral borders to a distance fully equal to one-fourth the entire width of the shell. The margins of the mantle have united ventrally, leaving a small posterior opening through which water can be forced, and a larger anterior opening through which the foot can be protruded. The region of the united margins of the mantle is occupied by a rather broad longitudinal muscle that spreads out around the anterior and posterior openings to form sphincters. The radial pallial muscles are also strongly developed. These extend from the calcareous margins of the shell to the free margins of the cuticle.

When the foot is protruded nearly to its full extent, and the pallial muscles are relaxed, the anterior opening is much larger than the foot, and through it water can freely enter the mantle chamber. When the foot is partially retracted and the sphincter muscle around the anterior opening contracts, this channel is entirely obliterated. A strong contraction of both longitudinal and radial pallial muscles, and a further retraction of the foot, fold the mantle and the elastic cuticle into the mantle chamber. At the same time the contraction of the adductor muscles bring the calcareous margins of the shell nearer together, and the mantle chamber is nearly obliterated. As the anterior opening has been closed, the water contained in the mantle chamber is driven through the small posterior opening. Relaxation of the pallial muscles and protrusion of the foot again affords ample opportunity for water to enter the mantle chamber, and the elastic cuticle expands this chamber to its greatest capacity.

By means of the jets thus formed animals frequently swim some feet before settling to the bottom.

Most lamellibranchs possess the power of sending jets of water from the mantle chamber, but they generally depend upon forcibly shutting the shell. Pecten and others swim by means of currents produced in this way, but with most it seems to do little more than free the mantle chamber of dirt. Other forms such as the soft clam, *Mya*, send very strong jets out of their siphons, and depend upon the contraction of muscles in the mantle as well as on closing the shell, to do it.

Until something further is known about the life and feeding habits of Solenomya, we can hardly expect to know the full significance of this mode of expelling water. Very possibly the jets are of value in cleaning the mantle chamber and burrow, and the animal has made use of them secondarily as a means of locomotion.

The ciliary mechanism in the branchial chamber of the pelecypoda: J. L. Kellogg.

The fact is well known that minute particles of matter suspended in water, whether they are to be used as food or not, are, upon coming in contact with the surface of the gills; driven forward and transferred to the inner surfaces of the palps. By these organs they are passed, in the same manner, to the mouth.

It is usually assumed that the animal is able to control this automatic process of filling the digestive tract only by closing the shell and thus preventing the ingress of water bearing suspended matter. There exists, however, a complex mechanism, differing in many respects in different species, by means of which suspended particles may be removed from the body, while water necessary for respiration (especially in active forms such as *Yoldia*) still continues to flow into the branchial chamber.

This mechanism in the common soft clam, *Mya*, may be described briefly as follows:

(1) There is to be found a complete ciliation of the inner surfaces of the mantle folds. Cilia drive foreign bodies from all points of these surfaces to vortices (one on either mantle fold), situated at the side of the opening for the foot in the fused mantle edge, anteriorly. The vortices are within reach of the palps, and food here collected may be taken by them. If the accumulated matter is not desired, the mass eventually falls upon a ciliated tract which carries it posteriorly along the ventral median line of the fused mantle edges, to a bay at the base of the branchial or *incurrent* siphon. From this point it is lost from the body, by the violent contractions of the adductor muscles, resulting in the discharge of the greater part of the water contained in the branchial cavity.

(2) The general ciliation of the surface of the visceral mass causes a movement of particles to a vortex opposite the base of the branchial siphon. Perhaps if desirable, this material upon the surface of the

visceral mass may be transferred to the inner surface of the mantle, referred to above. If not, it is discharged through the branchial siphon on the contraction of the adductor muscles.

(3) Gills, as is well known, collect matter and conduct it forward along a ventral groove to the palps.

(4) The inner surfaces of the palps bear ciliated ridges. In a peculiar manner, the cilia of the ridges drive particles to the mouth. Around the entire margin of the palp is a tract on which the ridges do not extend. Its cilia swiftly carry matter away from the mouth, throwing it off from the posterior, free tips of the palp, into the branchial chamber. Eventually this may be discharged from the body as previously described. By muscular movement these edges may be applied to any surface within reach, sweeping it clean of particles which it may be bearing, and casting the material into the branchial chamber.

In *Yoldia*, which lives in soft mud, the mechanism of the palp, though it performs the same general function, is very much more complex. The plate gills, also, which collect particles with amazing swiftness, may, if desirable, transfer them to the palps, or may be rid of the material by allowing it to pass up through a peculiarly constructed passageway between two plates to the epibranchial chamber, whence it is carried from the body by the stream of water continually being discharged through the epibranchial chamber.

This mechanism is very different in different forms, due to structural peculiarities of regions bearing cilia, and to the habits and needs of various species. We have facts sufficient to show that, without hindrance to the respiratory processes, Pelecypods have the power of collecting food by means of a very complex mechanism; or at will, through the muscular movement of certain ciliated surfaces, of removing any material which it may be desirable to prevent from entering the digestive tract. Data is being collected for a description of this mechanism in as many species as possible.

Observations upon the development of Phascolosoma. J. H. GEROULD.

The forms that were used for investigation were *Phascolosma gouldii*, *Ph. vulgare* (Blainv.) and *Ph. elongatum* (Keferst.) The ova which are ready for maturation are swept into the nephridia by the action of the cilia of nephrostome and of the internal surface of the nephridium. The eggs that are found within the nephridia, prior to their ejection through the nephridiopore, have the spindle of the first polar globule with ten rod-shaped chromosomes already formed. The astrosphere of the male pronucleus precedes the nucleus in the migration of both toward the center of the cytoplasm; it usually divides before the union of the two pronuclei. The segmentation nucleus contains twenty chromatic filaments which split longitudinally.

The alternating directions of the cleavage planes as far as forty-eight cells are identical with those in corresponding stages in the eggs of annelids, most molluscs, etc. The most striking peculiarity in *Phascolosoma* is the large size of the first set of 'micromeres,' which in quadrants A, B and C are distinctly larger than their sister cells at the vegetative pole. The 'macromeres' throughout the course of cleavage are of small size.

The mesoderm is derived from d^4, which in the one instance observed divided in harmony with the regular alternation in direction; its posterior derivative divided immediately to form a second mesoblast. In the divisions of the cells of the somatic plate deviations from the rule of alternation in the direction of cleavage were observed.

The rosette, cross and intermediate cells are established when the egg has only forty-eight cells. The rosette cells are very large; and the ciliated prototroch, which consists of sixteen cells, derived from the first set of 'micromeres,' forms a complete girdle around the egg.

A typical trochophore is formed, of which the plane of bilateral symmetry corresponds to a vertical plane bisecting *B* and *D* of the four-celled stage. A postoral circlet of strong cilia appear at a short interval behind the prototroch, and a long tuft of flagella is still earlier developed upon the apical plate. There is no true paratroch. Eye spots are present, and trochophores and larvæ are positively phototactic.

No traces of metameric segmentation manifest themselves throughout the course of development, which was observed continuously until the young worms had reached the age of seven weeks. This and certain other embryological facts seem to indicate that the *Gephyrea* are somewhat more closely related to the *Platyhelminthes* than to the *Annelida*.

Notes on the structure of Alma nilotica, a gilled earthworm from Egypt: P. M. Rea.

Alma nilotica Grube, has been known since 1855, but has never been thoroughly investigated. Its systematic position is uncertain, but the present research shows conclusively that it is an Oligochaete having many of the characteristics of the Geoscolicidae. The possibility of the identity of this form with the genus *Siphonogaster* of Levinsen increases the interest of this remarkable worm. The material available at present is sexually immature, but it is hoped that specimens collected in the spring will determine this point. A pair of ovaries has been demonstrated in segment 13 and testes in 10 and 11, but no evidence of the enormous penial processes of *Siphonogaster*.

The gills, which are the most characteristic feature of the worm, are out-pocketings of the body wall, taking with them the layer of circular muscles but leaving the longitudinal muscles behind. They are provided with afferent and efferent blood vessels. The epithelium of the gills and whole body surface is highly vascular. The dorsal blood vessel extends no farther forward than the seventh segment, where it ends abruptly in the most anterior pair of hearts. There is a supra-œsophageal vessel and two remarkable lateral vessels which will be more fully discussed in a later paper. Connected with the lateral vessels are numerous spherical acini, closely approximated to the inner surface of the body-wall, which appear to be identical with the structures figured by Perrier as occurring on the walls of the œsophagus in Perichaeta.

On the life history of Autolytus cornutus and alternate generation in annelids: P. C. Mensch.

The claim for alternate generation in annelids arises from investigation on the Syllidians, chiefly *Autolytus*. It was first suggested by Quatrefages and Krohn, but for the first time fully described by A. Agassiz for *Autolytus cornutus*. Agassiz regarded the parent stock as distinctly asexual and in this manner described a true alternate generation—the asexual parent stock alternating with sexual stolons.

The asexual condition of the parent stock is, however, not constant and the percentage of parent stocks with sexual products is sufficiently great to strongly indicate that the presence of reproductive products toward the close of the phenomenon of budding is a constant stage in the life-history of this Syllid. This being the case there would be, not an alternation of generation but at most only a sexual dimorphism.

Another aspect of this question is presented by the morphological characters of the stolon itself, in that the stolon does not attain the value of a distinct individual, as compared with the fission in other annelids (*Dero*, *Aeolosoma*), but the entire process is more like the sexual fragmentation described for the Palolo worm.

Metamerism of the Leech. W. E. CASTLE.

Following Gratiolet, most students of leech metamerism regard the annulus which bears the metameric sense organs as the first (most anterior) annulus of the somite. Careful study shows, however, that the sensory annulus is really the *middle*, not the most anterior ring of the somite.

The true limits of the somite are indicated by the distribution of the metameric nerves, all the annuli of a somite being innervated from one and the same ganglion. This is shown by the following facts:

1. In somite abbreviation rings innervated from the same ganglion fuse together.

2. In somite growth (multiplication of annuli) new rings appear chiefly at the limits of the somite (as defined), usually first at the posterior, then at the anterior end of the somite.

3. An abnormal animal, in which a somite is wanting in either half of the body, shows that the missing rings form a somite, limited as stated above.

The multi-annulate structure of the leech somite is correlated with the restricted number of somites in the body (thirty-four both in the Rhyncobdellidæ and in the Gnathobdellidæ). Increase in length of body and complexity of structure has been brought about not by multiplication of somites, as in the Chætopoda, but by elongation of existing somites and multiplication of their annuli.

Whitman and Bristol have established the derivation of the five-ringed type of somite from the three-ringed type; several facts indicated the probable earlier derivation of both from a one-ringed type of somite. Among these may be mentioned the manner of somite abbreviation and the structure of the somite in Branchiobdella and related forms.

The development of the pigment and color pattern in Coleoptera: W. L. TOWER.

The object of this research was to find out if possible: (I.) the way in which the colored patterns developed, and the sequence of the colors in ontogeny, (II.) the origin of the pigment and its development, (III.) something of its composition.

I. In Coleoptera two types of colorations are found.

(1) Unicolorous, where the whole animal is of one color.

(2) Multicolorous, where there is a color pattern of two or more colors.

I have studied the development of the color pattern in several forms of each type.

After the larva transforms to a pupa it is white or pale yellow. Color first appears on the cuticula of the future beetle about the opening of the spiracles, *i. e.*, where the spiracular muscles are attached to the cuticula. Color next appears upon the prothorax as two bands laterad of the median line, then a more or less broken band laterad of the first two appears, and last of all two spots at the anterior and posterior outer angles. The places where color first appears is over the attachment of the muscles to the cuticula. These spots may all become united as in the unicolorous, or remain separated as in multicolorous type forms. Color next appears upon the head, over the attachment of the cranial muscles to the cuticula, and then color appears upon the ventral abdominal surface over the muscular attachments.

The color as it first appears is pale yellowish brown which rapidly darkens, becomes very dark brown or black. This dark or black color is, according to Hagen, dermal pigment: There are some beetles that have a unicolorous type of color pattern but are yellow or orange in color. Yellow and orange are hypodermic colors according to Hagen. These beetles are few in number. I have not yet been able to get material to study one of these forms.

In all the beetles that I have studied color appears first over the origin or attachment of the body muscles to the cuticula. No color appears upon the wings until they are out of the pupa case and the wings are fully expanded. Then color appears first between the nervules as longitudinal bands which may become confluent, remain as bands or break up into rows of spots.

The pupa becomes first white (*i. e.*, a yellowish white), then yellow or ochre yellow, then the special adult colors develop so that the sequence of development is yellowish white (due to the color of hæmolymph), yellow, ochre yellow, yellow brown, brown, dark brown and black.

II. The pigment forms, first as a waxy transparent layer upon the surface of the cuticula. This waxy layer is excreted from hypodermal gland cells having openings upon the surface. This waxy secretion forms a secondary cuticula which is the pigmental cuticula; the primary (embryonic) cuticula is unpigmented.

After the waxy layer has attained a considerable thickness, it becomes darkened over the places where dark pigment is to develop. This layer is homogeneous without lamellæ or pore canals. Only dark, *i. e.*, black brown or dark red color appears to be formed in this secondary cuticula layer. Yellow is always formed from the precipitation of solids from the hæmolymph in or among the hypodermal cells.

If the hæmolymph is allowed to dry in the air, it becomes yellow brown in color, and when some quantity is allowed to dry it appears very dark or even black by reflected light. If hæmolymph is precipitated by heat, a yellow mass is thrown down, leaving an ochre yellow fluid, which can be decanted off. The yellow precipitate in sealed tubes bleaches on exposure to light. It also darkens on exposure to air. If O_2 be passed through the yellow liquid, it rapidly becomes dark brown, and on concentration by evaporation, leaves a waxy residue.

If the hæmolymph be mixed with .1% $HClHC_2H_3O_2$ or almost any acid, it becomes red, but the yellow color is restored by an alkali as .5% NH_4OH.

III. I have been unable to determine the composition of the pigment, owing to the difficulty of isolating it. I have made some tests upon the hæmolymph and have demonstrated Fe, Na, Mg salts, albumen, fibrin, globulin, xanthophyl to be present.

IV. Summary of results:

(*a*) On the body color (dark) develops first over the attachment of the muscles to the cuticula.

(*b*) The multicolorous type of color pattern is the least specialized; the unicolorous type having dark color is the most specialized, and the unicolorous yellow type is the most primitive of color pattern in Coleoptera.

(*c*) The pigment is situated in a secondary cuticular layer external to the primary cuticula which is unpigmented.

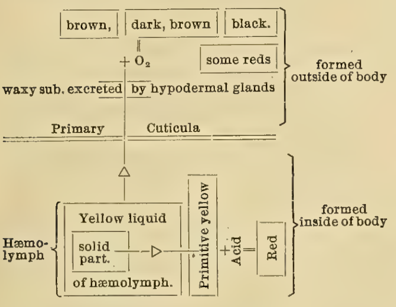
(*d*) The pigment is derived from the hæmolymph of the pupa. The dark pigments, black, brown and some reds are derived from the oxidation of a substance, elaborated from the more liquid part of the hæmolymph by the hypodermal gland cells. Yellow is due to the precipitation of the solid parts of the hæmolymph among the hypodermal cells.

(*e*) Yellow and red are the neutral or alkaline, and the acid modification of the same substance. This substance I believe to be like litmus in its reaction to acid and alkali.

Yellow is the more primitive color, while red is the acid differential of the yellow pigment. Acid may come from acid formed by metabolism (uric acid) or secreted by special cells.

Brown, dark brown and black are due to the oxidation of the yellow waxy pigment.

I may express the relation of these pigments in the following diagram :



Notes on mammalian embryology: CHARLES S. MINOT.

The author exhibited drawings, wood engravings made in Germany, and lantern slides illustrating the development of the pig. The work has been done in connection with the preparation of an 'Introduction to Embryology' for the use of students, intended for practical work. It is proposed to study a few of the most typical stages in a series of carefully selected typical sections, and to connect the descriptions of these sections with explanations of the relations of the embryonic organs to the adult anatomy on the one hand, and to the germ layers on the other. The principal engravings are being made by Probst in Brunswick, the author believing that the German method of wood engraving is better adapted to the representation of sections of embryos than are either the 'process' methods, or the American style of wood engraving.

On the spermatogenesis of Peripatus: THOS. H. MONTGOMERY, JR.

The spermatogenesis of *Peripatus balfouri* Sedg. is interesting, first, because it has essentially the type of that of Insects (as distinct from that of Crustacea as known for the Copepoda), and second, because the character of its cells is very favorable for the determination of the stages which occur in the synapsis stage (an anaphase of the last spermatogonic division). The reduction of the number of chromosomes (from 28 to 14) takes place in the early synapsis by a fusion end to end of every two chromosomes, those ends of the chromosomes joining together which are situated nearest that point of the cell where the centrosomes lie. Each resulting bivalent chromosome has the form of a U or V, whereby the bend or angle of the U or V is the point of union of two univalent chromosomes; this point of union is effected by a band of linin which appears to be a remnant of that continuous linin spirem thread present in the preceding prophase of the spermatogonic division. Later the two arms of each bivalent chromosome become longitudinally split. The chromosomes appear to preserve their separateness (individuality) during the following rest stage. In the first spermatocytic division each bivalent chromosome becomes transversely split (through the linin band joining its two component univalent chromosomes); in the second spermatocytic division each (now univalent) chromosome becomes longitudinally split. This account serves merely as a brief preliminary note to observations which will be soon published *in extenso*.

Palæmonetes and salinity; an experimental study in evolution: ROSWELL H. JOHNSON and ROBERT W. HALL.

A common shrimp on our Atlantic coast, *Palæmonetes vulgaris*, is provided with small spines on the beak or rostrum. These spines vary considerably in number on individual specimens, but the *average* number on specimens from salt water from different localities is quite constant, being about thirteen. When this shrimp is found in *brackish water*, however, the averages from different localities vary considerably, and *are always less* than the salt water average. In water which was nearly fresh, we have found the average to be as low as 9.61. Moreover, the decrease in the average seems to be in proportion to the decrease in density. This seems to show that such a character as rostral spinosity may be so correlated with the economy of the animal, that such a factor as salinity may determine it. The experiment of putting the animals from salt water directly into fresh water failed to show that those whose average number of spines was the least, had the greatest resistance capacity. Hence it is suspected that the direct action of environment, and not natural selection, is the method by which the evolution to the brackish-water form is accomplished. This question can be settled only by *rearing* the salt-water form in fresh or brackish water. The decrease in spinosity of the brackish-water form makes it seem probable that our fresh water species, *P. exilipes*, has been derived from *P. vulgaris*. The two species are very similar and, at least in respect to rostral-spinosity, intergrade perfectly; for the averages in *exilipes* are found to vary from 8.53 to 10.11, while *P. vulgaris*, as shown above, may have as low an average as 9.61. Experimentation may also throw light on the question as to whether *P. exilipes* has arisen as a variety in one place, and later spread, or has originated in different places under a common factor of environment—lessened density. In one case where the two forms were found inhabiting the same river (The St. Johns, Fla.), they were separated by a distance of only thirty miles, at most.

Variations and regeneration and Synapta Inhaereus.

The characters of this holothurian as described in systematic works, were subjected to quantitative analysis. The standard deviation, mean, mode and coefficient of variability were determined for 850 variates of the anchor and anchor-plates, 13 variations from the typical anchor and 20 variations from the typical anchor-plate were described. The typical anchor prevailed in 96.6% of the variates and the plate in 61.5%.

The specimens examined from Beaufort and Naples showed only one type, that of the described anchor and three types of plate with an adherence of $95\frac{3}{4}$% to the typical form. The specimens from southern waters are therefore least variable while the striking divergence is shown in the northern collections from Long Island, and Woods Holl with 18 types of plates, with 8 types of anchors showing spurs of various kinds, there is shown a tendency toward a place-mode at Lloyds Harbor, Long Island.

In one specimen from Centre Island, Cold Spring Harbor, Long Island, 61 3-7% of the variates belong to another than the type-pattern. Similar variations in the number of tentacles with their relation to the normal symmetry were noted. The mode of distribution of digits is three on the dorsal and ventral sides, respectively.

Nine out of 17 experiments on regeneration of the body and tentacles were successful.

The effect of strychnine on the unfertilized eggs of the sea-urchin: T. H. MORGAN.

When the unfertilized eggs of *Arbacia* are placed in sea water containing strychnine they will begin to segment in the course of three or four hours. Strychnine, either as an alkoid or as a sulphate, produces the same effect; the solubility of the latter being nearly a hundred times greater than that of the former. Saturated solutions were used. The eggs divide usually into a larger and a smaller part and the segmentation may continue through several subsequent divisions. The result is the same whether the eggs are left in the solution or whether transferred after two to three hours to sea water.

A certain time is necessary to start these changes in the eggs. Eggs left for one hour in the solution showed little subsequent segmentation, and even after one and a-half hours sojourn in the solution, only a few of the eggs divided after being returned to sea water. Richard Hertwig had shown that if the unfertilized eggs of a sea-urchin are put into sea water containing strychnine, that after a time the nuclear wall breaks down, a nuclear spindle forms around the chromosomes, and after division of the latter, a new nucleus reforms. My own results show that a nearly similar change takes place in *Arbacia*, but the chromosomes of many eggs separate after division and make two (or more) new nuclei. If this happens, a subsequent division of the protoplasm takes place.

The changes brought about by the strychnine have many points of resemblance to those that take place in the unfertilized eggs acted upon by certain salt solutions: magnesium, sodium or potassium chloride. In the latter instances I have tried to show that the transportation of the chromosomes is brought about by the astrospheres that appear in the egg and the number of new cells that form is, in general, in proportion to the number of astrospheres that are present in the egg. The latter being more numerous, produce a wider distribution of the chromosomes.

The absence of these astrospheres in the eggs acted upon by the strychnine accounts for the fewer divisions of the protoplasm in these eggs. All of these substances produce a slight shrinkage of the egg and it seemed not improbable that the cleavage of the egg might be the result of the plasmolysis, especially since the fertilized egg also sets free water or some other fluid at the moment the spermatozoön enters. In order to test this possibility I tried the effect of different strengths of magnesium and sodium chlorides—percentages ranging from those that do not affect the eggs to those that kill the eggs in a few minutes. The results show that isotonic solutions of these two salts produce very different results. The eggs will withstand a solution of magnesium chloride that was twice the strength of sodium chloride. This is the more surprising since the latter salt exists in sea-water in nearly ten times the quantity of the former.

The results also show that it takes a weak solution very much longer to act than a stronger one. The length of time being out of all proportion to the plasmolyzing effect of the solution. Further, a solution so strong that it will kill the eggs in half an hour, will cause the eggs to divide in several parts if they are left in the solution for five minutes and then transferred to sea-water.

In a previous paper I have compared the action of these substances to the action of stimuli on a nerve or a muscle. A large number of very different kinds of stimuli will start a nerve-impulse or a muscular contraction, the result depending more upon the structure of the living part than upon the stimulus employed. The unfertilized egg of the sea-urchin is likewise in a state of unstable equilibrium prepared to undergo a definite series of changes along given lines. These changes can be started in several ways, and resemble more or less perfectly the changes following fertilization, but I believe it would be as erroneous to compare the action of these substances directly with the process of fertilization as it would be to affirm that the action of a sudden blow on a muscle producing contraction is the same as the normal nerve impulse received through the nerve. The result is more or less the same because the same mechanism is set to work in the muscle or in the egg, but it would be misleading to infer that, therefore, the stimuli are themselves alike because they produce nearly similar results.

Reissner's fibre in the canalis centralis of vertebrates. PORTER EDWARD SARGENT.

Reissner in 1860 described in Petromyzon a cylindrical rod or fibre lying in the canalis centralis. His discovery was confirmed three years later by Kutschin who named it Reissner's fibre. Its presence has since been noted in a considerable number of fishes by three other investigators. By these it has been generally considered an artifact formed by the coagulation of the cerebro-spinal fluid.

Researches carried on during the past year has proved it to be a continuous fibre extending through the whole length of the canalis centralis and into the brain ventricles, and constituting an integral part of the central nervous system of *all* vertebrates.

As its posterior end Reissner's fibre gives off fine processes which pass peripherally between the epithelial cells forming the walls of the canal into the nervous substances of the cord. Anteriorly it extends forward through the fourth ventricle to the anterior region of the third ventricle, where after dividing several times each, division enters the torus longitudinalis posterior and ventral to the posterior commissure. Within the torus the divisions of Reissner's fibre divide many times, becoming eventually distributed to the ectal region of the optic lobes. In cross section the fibre shows a thin myelin sheath, and the central portion has a punctate appearance. Studniscka's recent deductions as to the nature of the fibre are shown to be incorrect and drawn from insufficient data.

The development in Amia and some other Teleosts has been worked out. Shortly after hatching some of the neuroplasts in the anterior portion of the optic tectum become differentiated, increasing greatly in size. By the second day after hatching these twenty to thirty cells send out processes which grow downward, penetrate into the third ventricle and growing posteriorly, coalesce to form Reissner's fibre. By the end of the second day this has grown posteriorly through the aqueduct of Sylvius and by the third day through the whole length of the canalis centralis.

SCIENTIFIC BOOKS.

Leitfaden der Kartenentwurfslehre für Studierende der Erdkunde und deren Lehrer bearbeitet von Prof. Dr. Karl Zöppritz *in zweiter neubearbeiteter und erweiterter Auflage herausgegeben von* Dr. Alois Blundau. Erster Theil: Die Projectionslehre. Mit 100 Figuren und zahlreichen Tabellen. Leipzig, B. G. Teubner. 1899.

The first edition of Zöppritz' 'Leitfaden der Kartenentwurfslehre,' a volume of 162 pages, appeared in 1884, and treated of projections, topographical drawing, plotting of itineraries and other matter more remotely connected with the construction of maps, such as the astronomical determination of geographical positions, constructions of geometrical curves, etc. The reputation of the author and the variety of contents secured a favorable reception to the volume, but it is a singular fact that its chief merit, that of opening a warfare upon the almost universal practice of misusing projections, should have been the least appreciated. Zöppritz was the first one in Germany who recognized the far-reaching importance of Tissot's investigations concerning distortions of projections and utilized them for his work, but the innovation was coldly received by German geographers. It was not until two years after Zöppritz' death, in 1887, that Hammer took up the fight and by his masterly translation of Tissot's mémoire succeeded in securing foothold for Tissot's ideas in the German scientific mind, and thus removed the last doubt about an ultimate victory of the principle "that the proper selection of a projection for a special purpose is not, like fashion, a matter of custom and taste, but dictated with analytical rigor," and thus prepared the way for a new edition of Zöppritz' 'Leitfaden.' The first part of this new edition, now in our hands, treats of projections exclusively and will be followed by a second volume, devoted to topographical drawing. No disparagement of the memory of Zöppritz is implied, but a tribute is paid to the sound judgment and industry of his successor, Blundau, for the proper assimilation of the new information and experience accumulated since Zöppritz' death, if I make the statement that the present edition is superior to the first one by a more exhaustive and systematic treatment of the subject in hand, by a general application of Tissot's tests and by the subordination of mere geometrical construction to computation.

The 'Leitfaden' was designed primarily as a guide to students and professors of German universities; and it is a significant indication of the conditions prevailing in these institutions, that Zöppritz should have deemed it necessary to apologize for the introduction of two or three formulas of spherical trigonometry, and that Blundau should make it a rule to avoid calculus; and in several instances, such as in giving the formula for equatorial distances in Mercator's projection, to rather omit the proof.

In passing over the contents of this volume in cursory review, I propose to pause only when meeting meritorious projections, which appear to have been neglected in this country, or such as recommend themselves to cartographers for special purposes.

Azimuthal projections.—This class of projections, although of considerable antiquity, has of late years become almost totally neglected. Many of them possess peculiar properties not found in any other projections which make them well suited for special purposes. Blundau introduces a very salutary departure from the usual practice of treating these projections separately by stating their common properties and the distinguishing features of each kind. It is a common property of all azimuthal projections that every point on the surface to be represented is shown in its true azimuth from a central point, and the distinguishing feature of each kind is the particular function of the spherical zenith distance of the point from the center of the map which is adopted as a measure of its distance, or $m = f(\delta)$, where m represents the radius or distance from the center of the map, and δ the zenith distance. The first projection coming under consideration is *Postel's*, in which the distances are given by the arcs

($m =$ arc δ). No projection can be devised which gives *all* distances correctly; Postel's gives the correct distance from one point, the center of the map; but for a limited area, even one as large as the United States which requires zenith distances of 21°, the error in distances is much less than in any of the other projections in common use, not excepting the polyconic, and it is to be greatly recommended for such maps as railroad and post-route maps. The most important one of these projections however is *Lambert's equivalent*, which gives distances by the chord ($m = 2 \sin \frac{1}{2}\delta$), because it gives true areas which for most ordinary purposes is the most desirable requisite. It would be most admirably suited for census purposes; for accuracy of distances it is inferior to the preceding one but superior to the polyconic. [For 20° zenith distance Blundau gives the elements of linear distortion for Postel's as follows: Tangential direction $a = 1.021$; central direction $b = 1.000$, and for Lambert's $a = 1.015$, $b = 0.985$.] In the *gnomonic* projection radial distances are given by the tangents of the zenith distances ($m =$ tang δ) it has the valuable property possessed by no other projection, that all great circles are represented by straight lines. For this reason it is a valuable adjunct to sailing charts, and the Hydrographic Office has published charts of all the great oceans on this projection. This is also a perspective projection with the point of view at the center of the earth. The *orthographic* projection, in which the sines of the zenith distances are taken as radii ($m = \sin \delta$) may also be regarded as a perspective one, it interests us only in so far as all lunar charts are constructed on it, in fact, cannot be constructed on any other. The *stereographic* projection which has the formula $m = 2$ tang $\frac{1}{2}\delta$ deserves mention on account of its antiquity, having been already used by Hipparchus (160–125 B. C.), and it is the only azimuthal projection which has no angular distortion or in which every circle is projected as a circle. It may also be treated as a perspective projection if the point of view is taken on the surface and the earth is assumed to be transparent; the map will then appear reversed like the type of a print. Amongst the conventional azimuthal projections I wish to call attention to one proposed by Hammer in Petermann's Mitt. of 1892, which consists of a Lambert's azimuthal hemisphere converted into a full sphere by a manipulation suggested by Aitow. This projection appears to be well adapted to replace the Mercator projections in atlases of Physical Geography, and has the advantage over Mollweide's, so often used for that purpose, that angular distortions are greatly reduced, besides being, like the latter, equivalent.

Conical Projections.—The transition of azimuthal projections into conical projections is effected by substituting the apex of the developing cone in the place of the center of the map, and by reducing the azimuthal angles in a common ratio, *i. e.*, multiplying them by a constant factor, which in the *ordinary conical projection* is the cosine of the polar distance of the tangent parallel. This *ordinary conical projection*, in which the central parallel and the distances between the parallels only preserve their relative values, while all other parallels and areas are exaggerated, should be used only where facility of construction is the principal, and accuracy a subordinate consideration. Two different methods are in use for compromising the exaggeration of the parallels. In the first one two parallels instead of one are given their true dimensions, one at half the distance between the lowest parallel and the middle one, the other at half the distance between the middle and highest parallel. The radii of the concentric parallels are prescribed by the condition that the latter shall retain their true distance from each other. This method is usually called that by an *intersecting cone*, which designation is misleading for the reason that the cone thus constructed is an ideal one which cannot be directly applied to the sphere; Blundau proposes to call it the *De L'Isle conic projection* after the French astronomer who made the first use of it. The second modification of the conical projection which is also frequently used in atlases, was devised by Mercator and should be called after him. Here also two parallels are given in their true dimensions, just as in the preceding projection, but the radii of the concentric parallels are not those of an ideal cone, but those furnished by a cone tangent to the middle parallel; the meridians no longer cross the parallels at right angles, nor do they meet in one point, the apex of the developed cone. By sacrificing the equidistance of the parallels, conical projections may be constructed which are either equivalent or conformal (without angular distortions) and yet retain either one or two true parallels. Lambert and Gauss have devoted considerable study to these projections; but there is one, devised by Albers in 1805, which has equivalence and two true parallels, qualities which should entitle it to special consideration, but hitherto it has not received any special trial. Amongst the pseudo or conventional conical projections, Bonne's occupies the first rank; although as long ago as 1880, Tissot exposed its glaring defects, it has nearly up to the present date retained almost undisputed possession of the principal atlases. This has sometimes been ascribed to *undue French influence*, but it may just as well be a consequence of custom and convenience. It is somewhat surprising that after all that has been said by Tissot and Zöppritz the 'Geodetic International Association' should persist in making use of Bonne's projection in their reports.

Transverse polyconic Projection of the United States
Drawn by A. Lindenkohl.

Regarding the *polyconic projection*, devised by the Coast Survey and very extensively used in this country, Blundau has not much to say that might be considered as very flattering. He says in substance that the distortion which in the equi-distant conic projections is most perceptible near the upper and lower borders is here shifted to the more distant parallels, and that it is of real advantage only when applied to the representation of regions of predominating meridional dimensions. It is a fact that in maps of the United States on this projection, like those issued by the General Land Office, the Geological Survey and the Census, the exaggeration of the meridians and areas near the Atlantic and Pacific borders reaches fully 6½ per cent., which is nearly three times as much as might be considered a fair allowance, and it seriously interferes with the use of these maps for the measurement of either distances or areas near these borders. But there are several methods by which the undoubted advantages of the polyconic projection can be preserved and its disadvantages greatly reduced, to which Blundau cannot be an entire stranger. One way would be not to adhere strictly to one central meridian, but in the case of an oblique map to shift the apices of the tangent cones in such a manner that the central meridians pass as nearly as may be through the middle of the map; the meridians would then assume a spiral shape. I have used this method on several occasions, but Hammer is the first one, I believe, who has called public attention to it. If the map should have a predominating east and west dimension, the developing cones may be applied in a transverse position; some great circle passing centrally through the map might be treated as a central meridian and the poles might be transferred to the equator. In the accompanying sketch I have constructed a projection of the United States on this principle; the 95° long. is substituted for the equator and the great circle, which in lat. 39°, is perpendicular to the meridian of 95°, is taken as central meridian. The distortion, which in an ordinary polyconic projection, accumulates near the right (east) and left (west) borders is here transferred to the vicinity of the upper (north) and lower (south) borders.* It may not be amiss to mention that for certain purposes Blundau has recommended the employment of abnormal conic projections, in which case the axis of the cone does not coincide with the axis of the earth and gives as illustration a map of Africa, in which the point in which the equator intersects the western coast of the continent is chosen as apex of the cone. On this projection the elements of distortion show very favorable conditions, but it has the serious defect of leaving a blank space by the complete development of the cone on a plane, and since Hammer has shown in Petermann's Mitt. of 1894, that just as favorable conditions may be attained by an equivalent azimuthal projection, the application of abnormal conic projections does not appear to deserve much encouragement. The *polyhedral* projection has a trapezoidal shape. It is now generally adopted in Europe for the single sheets of serial publications of government surveys on a large scale (between 1/20000 and 1/100000); it is similarly used by the U. S. Geological Survey, and has been proposed by Penck for the prospective map of the world on the one millionth scale. It is the shape which any part of the earth's surface, enclosed by two parallels and two meridians will assume in many kinds of projections now in use, provided the size of the section is small enough (not more than 15 or 30 minutes or one degree of latitude and longitude) to allow the substitution of the chord for the arc of the parallels. Consequently this so-called polyhedral projection, properly speaking, is no projection at all; the separate sheets may be joined in different ways, such as will conform to either a polyconic or to a simple tangent conical projection.

Cylindric Projections.—The transition from conic to cylindric projections takes place when the constant factor (n) of the azimuthal angle becomes 0. In this case the meridians become straight parallel lines and the contact occurs at the equator. This great circle as well as the parallels appear also as straight lines, intersecting the meridians at right angles. These conditions are common to all cylindric projections, and the only difference between the several varieties consists in the particular function of the latitude $y = f(\phi)$ which is adopted as measure for the distance of the parallels from the equator. If the meridional arcs are given in their true dimensions ($y = \text{arc}\ \phi$) we have the *square* projection which should not be used for more than 15° from the equator. For broader zones an 'intersecting' cylinder should be substituted (corresponding to the intersecting cone of the De Lisle's projection) which will transform the square into a rectangular projection. The cylin-

* In the polyconic projection the lines of equal linear (and areal) distortion are parallel to the central meridian, and the distortion for modern distances increases as the square of the distance from this line. [Distortion $= 0.01\left(\frac{\Delta}{8^\circ.1}\right)^2$ where Δ = distance from central meridian in degrees of arch of great circle.] Since the distance across the United States from north to south, is only about three-fifths of that from east to west, it follows that by the above manipulation the maximum of distortion is reduced from 6½ per cent. to about 2½ per cent.

der may also be made tangent to a meridian instead of the equator by which the square projection is changed into Cassini's, which, for moderate distances from the central meridian, greatly resembles the polyconic. Cylindric projections may also be made equivalent ($y = \sin \varphi$), when we obtain Lambert's equivalent cylinder projection, but it is only when it assumes that shape (called *conformal* by Gauss and *autogonal* by Tissot), in which there is no angular distortion, or in which the elementary arcs of longitude and latitude preserve their relative dimensions, when $y = \log$ nat. tang $(45° + \frac{1}{2}\phi)$, that this projection, as the Mercator, has attained an importance which puts all others into the shade. The vexatious question of nearly fifty years standing whether the Mercator or polyconic projection offers greater advantages for hydrographic charts, does not appear to have been finally settled yet. Granting that sailing by the *orthodrome* is preferable to sailing by the *loxodrome*, and that the polyconic gives the *orthodrome* in a more nearly straight line than the Mercator, this departure from a straight line may assume sufficient proportions to render the polyconic chart unreliable while, with the positive knowledge that, with the exception of Meridians and the equator, all great circles are curves on the Mercator chart, no sailor will meet with any difficulty in laying down *orthodromes* on a Mercator chart without calculations with the assistance of a gnomonic chart; but the chief argument in favor of Mercator charts will always remain the facility of laying down positions and courses. For hydrographic charts which are not intended to be used as sailing charts, or which are on such large scales that the sea area occupies but a narrow margin, the employment of theMercator projection should be avoided for the reason that the differences within the narrow limits between the two contending classes of projections are sufficiently small to allow the use of a polyconic for the same purpose as the Mercator chart, but they are great enough to render a Mercator chart unfit for most of the uses a map may be put to, such as the measurement of distances and areas. Another very extensive use to which the Mercator projection has been put is for planispheres in atlases, especially for the purpose of disseminating and illustrating information of a statistical or physical nature, and here Blundau is slightly mistaken if he assumes that in this capacity it could very properly be superseded by projections of less objectionable features. For many purposes, for meteorological charts for instance, it is of greater importance to have the cardinal directions, north and south, east and west always point the same way and remain parallel to the borders of the chart, than to have correct areas and to have these lines run in every possible way. The objection so frequently raised against the Mercator projection that it does not furnish any indications for the courses of great circles, may readily be overcome by constructing on transparent paper a system of great circles which intersect the equator in two opposite points. If, however, the Mercator chart is used to illustrate conditions in which correctness of area is more important than parallelism in identical bearings, like those showing density of population, or the distribution of animals and plants, it may very properly be superseded by others of an equivalent nature; if no other, by Mollweide's which is very easily constructed, and always available.

The closing chapter about projections treats of the selection of one with least distortion and gives a résumé of the results of Tissot's investigations with tables giving the relative values of the elements of 'deformation' for the principal projections in use, reducing the formerly often troublesome question about the relation of a projection for a special purpose to one of easy solution. But this applies only to maps embracing large areas, as those of continents; the question about the projection with least distortion for areas of restricted size, such as European countries, does not admit of a general solution, but has to be solved for each country separately and this solution is definite. In no such case would the projection be one admitting geometrical construction; it would be one entirely dependent upon analysis.

Having carefully perused the volume from beginning to end, I conclude that it is an eminently practical book and gives to the cartographer all the information he may possibly need regarding the nature of projections and their constructions; but it is because of this utilitarian tendency, together with Blundau's manifest aversion to cross the threshold of higher mathematics, that to the disciples of Gauss, Lagrange and Tissot (who care more for the theory than for the application of projections), the treatment of 'autogonal' or 'conformal' projections is not altogether satisfactory. He should have introduced the elements of the theory of functions without which a proper treatment of these projections is impossible. He should at least have said that the coördinates of a sphere (u, v) are connected with those (x, y) of Mercator's projection by the relation

$$x + iy = u + i \log \operatorname{tang} \left(\frac{\pi}{4} + \frac{v}{2}\right)$$

and that by suitably taking Φ, the coördinates of any other autogonal projection (X, Y) are given by the relation

$$X + iY = \Phi\,(x + iy).$$

If $\Phi(\ \ ) \equiv e^{\pm i(\ \ )}$ a stereographic projection is obtained in which the north or south pole is the center of the map. If to this stereographic projection we apply $\Phi(\ \ ) \equiv -K + \mathrm{cn}^{-1}(\ \ )$, we obtain Peirce's *quincuncial* projection, etc.

A. Lindenkohl.

December 28, 1899.

The Evolution of General Ideas. By Th. Ribot. Translated by Frances A. Welby. Chicago, Open Court Publishing Company. 1899. Pp. 231.

The scope and mode of treatment of Professor Ribot's monographs are well known; and this one follows closely the general plan of those which have preceded it. The topic itself is a most interesting one; the genesis of the powers of abstraction and the evolution of the general ideas which represent the fruit of such abstraction. The material for the early forms of the process is to be found in the mental operations of animals, of children and savages, and of deaf-mutes before education. These have, in common, the absence of words and the dependence of the abstraction upon the generic images formed by sense-experiences. The intermediate stage involves the use of words and is reflected in the character and growth of language. The word fixes the material basis of the abstraction and aids the mind in focusing upon the 'abstracted' relation. In the highest stages of abstraction the element of representation has faded away, and the word practically constitutes its entire content. Following the description and illustration of these processes is a special consideration of the development of the special concepts of number, space, time, cause, law and species. The fundamental insistence upon experience as the basis of such development and the suggestiveness of the genetic point of view find apt application in this part of the thesis.

But in spite of a well-chosen theme and of a discerning utilization of the literature; in spite of much interesting material and suggestive modes of treatment, the general impression of the book is a rather unsatisfactory one. There is a judicious occupation of points of advantage; skirmish lines are thrown out in various directions, a campaign is carefully planned—and the planning is rather too freely discussed—but there is no vigorous nor successful attack upon the real stronghold of the situation. None the less, the monograph will be a helpful one to the student, who will appreciate the significance of the problem, as Professor Ribot outlines it, and who will be led by the interest of the exposition to assimilate the essential factors involved in the growth and functioning of the powers of abstraction. His attention may be specially directed to a point touched upon in the last chapter, but worthy of more extensive treatment; namely, that the criterion of the utility of abstraction is not to be sought merely in its products—such as the higher mathematics or metaphysics—but as well in the process itself, by which the individual learns to focus the attention at will upon any aspect of a complex experience which may become important. And, in the same chapter, he should not overlook the suggestive delineation of the parts played by theory and practice, by the incentive of genius and by gradual development, in the actual history of the sciences depending upon abstraction.

Of the translation, the best that can be said is that it is barely satisfactory. A good translation of a psychological work involves the absorption and re-expression of the author's perspective of ideas, not of his words alone;

abundant Latinisms, ambiguous phrases, and awkward statements reveal that this process has not been very successfully accomplished in the present instance.

SCIENTIFIC JOURNALS AND ARTICLES.

THE New York Botanical Garden has begun the publication of a monthly journal to contain notes, news and untechnical articles of general interest. It is edited by Dr. D. T. MacDougal, director of the laboratories, and is sent free to members of the Garden. The first number, containing sixteen pages, opens with an article on the Museum building by Dr. N.L. Britton, with a plate, and this is followed by short unsigned articles on 'Coöperative Forestry,' 'Etiolated Plants as Food,' 'Micorhizas of Orchids' and 'Colors.' At the end there are notes on recent accessions to the Gardens and on other subjects of botanical interest. The New York Botanical Garden now has four series of publications. The *Journal* just mentioned, the *Bulletin*, containing official documents and technical articles, *Memoirs* and *Contributions*, the latter being reprints from other journals.

THE December number of the *Bulletin of the American Mathematical Society* contains a report of the October meeting of the Society, by the Secretary; 'Note on the Simply Transitive Primitive Groups,' by Dr. G. A. Miller; 'On the Commutators of a given Group,' by Dr. G. A. Miller; a review of Oltramare's 'Calcul de Généralization,' by Professor E. O. Lovett; 'Shorter Notices'; 'Notes'; 'New Publication.' The January number of the *Bulletin* contains the Presidential Address of Professor R. S. Woodward. 'The Century's Progress in Pure Mathematics,' delivered at the annual meeting of the Society, December 28, 1899; 'The Status of Imaginaries in Pure Geometry,' by Professor Charlotte Angas Scott; 'Notes'; 'New Publications.'

SOCIETIES AND ACADEMIES.

GEOLOGICAL SOCIETY OF WASHINGTON.

AT the 94th meeting and 7th annual meeting, held December 13, 1899, the following officers were elected for the ensuing year: *President*, Whitman Cross; *Vice-Presidents*, J. S. Diller, C. W. Hayes; *Treasurer*, M. R. Campbell; *Secretaries*, F. L. Ransome, David White; *Members-at-large of the Council*, G. P. Merrill, Bailey Willis, A. H. Brooks, Waldemar Lindgren, G. O. Smith.

THE 95th regular meeting was held January 10, 1900. Under informal communications Mr. G. P. Merrill exhibited and briefly described a nepheline-melilite-basalt from Rocky Hill, Oahu, where it had been found in place by Professor C. H. Hitchcock. It was stated that while a rock of this type had been previously described by Wichmann and others from fragments brought by vessels as ballast, this was, it was believed, the first discovery of the rock in place.

Under the regular program the following papers were presented:

(1) Mr. Joseph A. Taff: 'Structural Features

of the Ouachita Mountain Range in Indian Territory.'

This mountain range is 200 miles long and trends west from the vicinity of Little Rock, Arkansas, into Indian Territory. It is separated from the Ozark uplift on the north by the east and west trough of the Arkansas valley. It is abruptly terminated on the east by the Tertiary overlap of the Mississippi embayment. The Cretaceous peneplain comes up on the south side of the range and Cretaceous rocks conceal much of the structure. On the west the strike of the folds turns toward the south, and the latter pass under Cretaceous sediments. As far as known, the rocks involved in the Ouachita uplift are Silurian shales, sandstone, limestone, and novaculites—2560 feet; Lower Carboniferous (Branner)—18,480 feet; and Upper Coal Measures—5300 feet; making a column nearly five miles in thickness. The sandstones become thicker and coarser toward the south.

The structure of the range is Appalachian. In the center of the range the folds, in massive sandstone, are wide and long. Near the periphery the folds are shorter and generally overturned, compressed and faulted. Some of the faults have vertical displacements of several thousand feet. The uplift began before or during the Carboniferous and culminated after that period.

(2) Mr. Geo. P. Merrill: 'The Gem Mines near Bakersville, North Carolina.' Specimens were shown and a brief account given of the pegmatitic veins in which the beryls (emeralds and aquamarines) occur.

(3) Mr. Arthur C. Spencer: 'A Peculiar Form of Talus.'

In some of the high basins of the San Juan Mountains, Colorado, the encircling cliffs have supplied at certain points an excess of débris, which has advanced across the floor of the glacial cirque as a tongue, simulating the form of a small glacier. The slope of these lobes may be as low as one in six, and their thickness may reach fifty feet. The surface of the talus-stream shows, in each case, a series of roughly concentric ridges, suggestive of differential and periodic downward movement. The chief force involved has doubtless been gravity, acting upon the mass of loose rock. The movement within the mass may, however, have been facilitated by interstitial ice derived from sifting snow or percolating water.

F. L. Ransome,
David White,
Secretaries.

BIOLOGICAL SOCIETY OF WASHINGTON.

316TH MEETING, SATURDAY, JANUARY, 13TH.

W. R. Maxon exhibited an abnormal flight feather from the peacock, in which the shaft was double for nearly its entire length.

William Palmer exhibited a series of specimens of *Onoclea sensibilis* showing variations due to conditions of environment, such as shade, exposure to light, moisture or dryness.

Vernon Bailey told 'Where the Grebe Skins come from,' and how the birds are killed by thousands among their nests on the lakes of eastern Oregon and California. Three species, the western, the eared, and the pied-billed grebe were found breeding among the tules in the shallow waters of Tule Lake, California, and here the hunters were engaged in shooting the old birds, stripping the skins from their breasts and shipping them to San Francisco. From twenty to fifty cents were received for a skin and the hunters were making from twenty to thirty dollars a day. At the present rate of destruction the birds will not last many years and the speaker raised the question, can they not be protected?

William Palmer spoke of 'the Ferns of the Lower Shenandoah Valley,' illustrating his remarks by specimens, showing their variation as compared with similar species from the vicinity of Washington due to the conditions under which they grew. In the case of every species but one the valley habitat was the dryer of the two resulting in the production of narrower fronds and less herbaceous plants. The deforestation of the valley and the grazing of sheep and cattle have caused the almost complete extermination of ferns, except in favored and very rocky localities, among the limestone bluffs and mountain streams. Many species common about Washington, and growing luxuriantly in wooded situations, were either absent or represented by few examples and these reduced in size and starved.

J. W. Daniels described 'Zoological Collecting in Cuba' speaking of the richness of the fauna and the difficulties that attended the work owing to the thickness of the vegetation.

E. L. Morris presented 'a Revision of the Species of *Plantago*, commonly referred to *P. Patagonica* Jacq.' stating that a number of distinct species had been combined under this name or its variety *gnaphalioides*, some of which were as yet undescribed. The species could be divided into two groups, distinguished by the form of the bracts, *Plantago Patagonica*, the speaker stated did not occur in North America.

T. W. STANTON,
Secretary.

WASHINGTON CHEMICAL SOCIETY.

THE regular meeting was held on January 11, 1900. The following officers were elected for the ensuing year: *President*, Dr. H. C. Bolton; *Vice-Presidents*, Mr. V. K. Chesnut, Dr. Peter Fireman; *Secretary*, Mr. William H. Krug; *Treasurer*, Mr. W. P. Cutter; *Executive Committee*, the above officers and Messrs. Wirt Tassin, E. E. Ewell, H. N. Stokes, F. K. Cameron and W. F. Hillebrand.

WILLIAM H. KRUG,
Secretary.

THE NEW YORK SECTION OF THE AMERICAN CHEMICAL SOCIETY.

IN addition to the program as announced for the January meeting of the New York Section of the American Chemical Society, Dr. George F. Barker, of the University of Pennsylvania and a past president of the Society, was present and made a very interesting address on the more recent developments growing out of the Röntgen ray investigations, describing and exhibiting a sample of radium or 'Radio-Active Substance A,' as named by the German chemists who are working on the subject. This substance emits rays which cause an impression of feeble phosphorescence to the eye, but which are not light. In other words, they are rays which cannot be reflected nor refracted. Nor can they be prevented from acting on a photographic sensitive plate by three thicknesses of black paper added to as many thicknesses of orange yellow paper; and images were shown on a plate which had been made through all this thickness of protective covering.

Few people have had the opportunity of seeing this substance, and Professor Barker's address was listened to with the closest attention.

Mr. Allen Hazen exhibited lantern slides 'Illustrating Filters for Purifying Public Water Supplies,' many of them taken in different foreign cities, but the largest number showing the process of construction and the finished work of the immense covered filter beds at Albany, which are capable of delivering about 9,000,000 gallons a day.

J. A. Mathews read a paper on 'Laboratory Method for Continuous and Uniform Generation of Acetylene and its Purification' and 'Upon the Carbide of Gold'; C. W. Volney, 'On the Reactions of Alkalis with the Cellulose Nitrates.

Dr. McMurtrie, the recently elected president of the society at large, was present, and made a short address, expressing his appreciation of the honor conferred by his election, and the hope that he would receive the hearty cooperation of all the Sections of the Society.

Nearly one hundred members and friends were present, and the first meeting of the new year gives promise of increasing interest and enthusiasm in the work of the Section and of the Chemists' Club, the rooms of which prove so satisfactory for the purposes of the Club as well as for the meetings.

DURAND WOODMAN,
Secretary.

ZOOLOGICAL CLUB, UNIVERSITY OF CHICAGO.
MEETINGS OF OCTOBER AND NOVEMBER, 1899.

AT the first session of the Club on October 18th a paper entitled, "The Significance of the 'Spiral Type' of Cleavage" was read by Mr. C. M. Child. The paper was the result of observations upon the cleavage of *Arenicola* and *Sternaspis* supported by a comparison with the cleavage of other forms which show the same type. The principal points urged are briefly as follows: the cleaving egg must be regarded as an organism, not merely as a cell colony or cell mosaic. Differentiation and cell division, even in the spiral type of cleavage, are independent phenomena, though they may coincide more or less closely in point of time. The spiral type must have been originally due to mechanical causes, but is certainly, at present, hereditary. It is followed by a bilateral form of cleavage which is morphogenetic in character, *i. e.*, the direction and time of division and the size of the cells all contribute directly to the establishment of form in the embryo. This bilateral cleavage has encroached upon the preceding spiral period in consequence of a condensation of the process of development. The determinate character of the cleavage makes possible the massing of large amounts of material in certain cells, which thus become centers of distribution, but this segregation is quantitative rather than qualitative so far as 'organ forming material' is concerned. An adequate conception of the extreme plasticity of the cell is necessary for a satisfactory interpretation of the phenomena of spiral cleavage.

The second session of the Autumn Quarter was held November 1st. Mr. R. H. Johnson read a paper reviewing and criticising some of the recent statistical literature upon the subject of variation. A second paper was contributed by Mr. E. R. Downing reviewing the experiments of Loeb, Morgan and others on the production of cell division and development in unfertilized eggs by chemical reagents.

At the third session, November 15th, Mr. J. M. Prather contributed the results of his study upon the development of the hypophysis in *Amia.* The hypophysis arises about one hundred and sixty hours after fertilization, as a local differentiation of hypoblastic cells in the dorsal wall of the fore-gut far back of the point of union of fore gut with stomodæum. Here the base of the fore-brain is in very close contact with the hypoblast, and this fact indicates that its point of origin is determined by physical factors. Lobes begin to form about the fifteenth day and by the thirty-fifth day the organ is much lobed, chiefly around the edges. The first lumen appears near the center during the ninth day, while others form in the lobes as they arise. The lumina appear to have no communication with each other or with the exterior. Neither blood-vessels nor nerves, nor glandular secretions could be found in it at the latest stage examined. The saccus vasculosus begins to form about the tenth day, as an evagination at the posterior lower angle of the infundibulum and grows backwards under the base of the hind-brain. It is thus quite remote from the hypophysis at all stages. Granular secretions were found in it as early as the twenty-second day. It is inferred that what Kupffer considered the earliest stage of the hypophysis in *Acipenser* is the anterior diverticulum of the fore-gut which is metamorphosed into the adhesive organ.

The second paper, read by Miss Anne Moore, was an account of the morphology and life history of *Dinophilus*, *D. Gardineri*, found at Woods Holl. Miss Moore succeeded in observing the actual encystment of *Dinophilus*, thus accounting for the sudden disappearance of the animal noted by other authors.

The fourth session, November 29th, was devoted to a paper by Mr. V. H. Lowe entitled, 'Photographing Insects and other Animals.' Mr. Lowe described in detail the apparatus and methods employed in photographing animals in the field and in the laboratory, including both living and mounted specimens. The paper was illustrated by a number of the author's lantern slides.

C. M. Child.

OTTAWA FIELD-NATURALISTS' CLUB.

The third of the series of Winter Soirées was held in the Assembly Hall of the Y. M. C. A. on January 9th. There was a good attendance of members and strangers. Zoology, ornithology and geology formed the topics of the evening. Professor E. E. Prince, B.A., F.L.S., Commissioner of Fisheries for Canada gave a most instructive paper 'On the Comparative Anatomy of the Ear,' in which he traced the unity of arrangement in the structure and mechanism of that organ from the lowest organism up to the highest, specially adapted to receive vibrations and impart them to the nerves connected therewith. By means of a beautiful series of exquisitely prepared original slides thrown upon the screen, Professor Prince illustrated the anatomy of the 'true ear' in jelly-fishes, mollusks, birds, fishes, snakes and vertebrates. An interesting discussion followed this paper in which Messrs. Kingston, Evans, R. B. Whyte, besides the lecturer, took part.

Mr. Andrew Halkett of the Marine and Fisheries Department, then read his paper 'On Gannets and Cormorants, with special reference to Canadian forms.' His paper was full of interesting notes of observations in the field and on the shores of the Atlantic and Pacific in British North America.

(1) 'Note on the Occurrence of *Remopleurides* in the Upper Trenton (Ordovician) of Ottawa, Canada; (2) 'On a new species of *Turrilepas* from the Trenton limestone of Governor's Bay, Ottawa, Canada,' are the titles of two brief papers presented by Dr. H. M. Ami. Brief descriptions of each were given and the salient points of dffference between them and their nearest allies indicated. The *Remopleurides* is new and nearer *R. Canadensis*, Billings of the Chazy, whilst the *Turrilepas* (opercular valve) is distinct from the only form known from the Ordovician of the Ottawa Valley, viz.: *Turrilepas Canadensis* Woodward, described in 1880, from the Utica formation.

Dr. Ami then drew the attention of the members present to Professor W. H. Hobb's paper 'On the Diamond Field of the Great Lakes,' a subject of considerable importance, and gave an abstract of the results reached from a careful scientific enquiry into the facts relating to the eight specimens of diamonds discovered in glacial and other gravels of Wisconsin, Ohio and Michigan—in material which came over during the glacial period from Canada. This paper was illustrated with lantern slides as was also the next 'On the Principal Places of Geologic Interest about Ottawa,' in which several interesting sections were given and the attention drawn to work still remaining to be done. Mr. A. E. Barlow's paper 'On the Bridgewater Conglomerates,' was taken as read owing to the absence of the author from town. Interesting discussions took place on the specimens exhibited at the meeting and other points of interest in connection with the papers read.

DISCUSSION AND CORRESPONDENCE.

BUCKLEY ON THE BUILDING AND ORNAMENTAL STONES OF WISCONSIN.*

PROFESSOR MERRILL'S review of this book I have read, † and in some respects it seems to me to do an injustice to Dr. Buckley.

A State Geological report may be reviewed from the point of view of the citizens of a state, or as a report primarily designed for scientists. It is the latter view which Mr. Merrill, who is connected with a national institution, has naturally taken. The book is objected to upon account of its size. This criticism is perfectly justified from the point of view of general science. However, the citizens of the State of Wisconsin interested in the stone industry desire detailed descriptions and tests of the stones furnished by each of the important quarry centers of the State. Therefore the publication of this material is fully justified in a State report. Of course, the reader who is interested only in science may omit this part of the subject.

In respect to crushing strength tests, of which Mr. Merrill speaks so lightly, whether he is right or not in reference to their uselessness, they must be made in order to promote the building stone industry in a state, for the strength of a stone is one of the questions which an architect invariably asks, and therefore one which the owner of the quarry must be able to answer provided he wishes to put his stone on the market.

Moreover, beside being justified on account of the local value, Dr. Buckley's strength tests do contain material which is of general scientific interest. For instance, Dr. Buckley finds that a number of the limestones of Wisconsin have the enormous crushing strength of 30,000 to 40,000 pounds per square inch (p. 392). Also a number of granites in Wisconsin have crushing strengths which run between 40,000 and 50,000 pounds per square inch (p. 390). The strengths of these rocks are unparalleled by any previous rocks tested. They therefore have an important bearing upon the general scientific question of the depth of the zone of fracture.

* Bull. No. IV. Economic Series No. 2. Wisconsin Geological and Natural History Survey. 1898.

† SCIENCE, N. S., Vol. XI., No. 262, pp. 24–25.

Of Dr. Buckley's explanation, p. 383, of the unfavorable action of freezing temperatures, Mr. Merrill says there is 'an unconvincing air of freshness.' For my own part, I think Dr. Buckley is correct in his explanation of the resistance which many porous rocks, like sandstones, exhibit to alternate freezing and thawing, while other rocks which may contain no more than one per cent. of pore space suffer severely under such conditions. This matter cannot be fully expounded in this review, but Dr. Buckley's explanation in brief is that in rocks in which the pore spaces are large and connected, the water is drawn off or distributed by capillarity, leaving the pore space only partly filled by water. When this water freezes there is room for expansion within the pores without rupturing the rocks. On the other hand, in some rocks in which the pore spaces are very small and discontinuous, the pores remain entirely filled by water, and when they freeze the expansion ruptures the rock (pp. 20–25, 374–375). Dr. Buckley's conclusion is fully warranted by his experiments, which show that fine-grained, compact limestones and granites which have a very small pore space, often lose more in strength by freezing and thawing than do the sandstones having a large percentage of pore space. I am not aware that experiments have before been made which show the actual effect of freezing and thawing on the strength of the rocks. Nor have experiments shown the relation of the size of the pores to the diminution in strength due to freezing and thawing, and Dr. Buckley's results on this point are believed to have economic value. However, whether this be so or not, they have a scientific value bearing on the disintegration of rocks in the belt of weathering.

Another matter discussed, upon which Dr. Buckley has made a contribution of general value to the science of geology, is the more accurate determination than has heretofore been done of the pore space of rocks. Tolerably well indurated sandstones he finds to vary in pore space from 10 to 20 per cent., or more, and in one case, that of the Dunnville sandstone, the pore space is over 28 per cent. (pp. 402–403). These results are of great importance as showing the actual amount of material which must be added by underground waters in order to completely cement a rock. From Dr. Buckley's results it is a safe inference that in the cementation of clean sandstones to quartzites, there must have been contributed by underground waters at least one-quarter of the entire volume of the rocks. In determining the pore space of building stones, their specific gravities have also been obtained by a method more accurate than has heretofore been used.

Dr. Buckley's observations on joints in the State of Wisconsin (pp. 458–459, Pl. 49) have an important bearing upon structural geology. These observations are shown upon the map and indicate that the dominant joints of the sedimentary rocks of Wisconsin are in nearly vertical position and in two sets nearly at right angles to each other, trending NW–SE and NE–SW. The position of these joint systems with reference to the folding has an important bearing upon theoretical structural geology which cannot here be discussed. In connection with certain structural work of my own I have searched for such information in many volumes, but nowhere else have I found a set of observations upon joints over so wide an area.

In conclusion it seems to me that the size of Dr. Buckley's book is justified by the necessity of putting in a State report the information which the people of the State wish. It seems to me further that the report differs from a number of previous State reports in containing considerable material which is of general value to geology.

C. R. Van Hise.

HYDROSTATIC VS. LITHOPIESTIC THEORY OF GAS WELL PRESSURE.

The paper read at the Orton Memorial Meeting at Columbus, entitled 'Edward Orton Geologist,' and published in Science, January 5th, contains a reference to Professor Orton's theory of nature of gas and water pressure in gas wells that calls for some comment.

The writer has for some time not been entirely satisfied with the 'Hydrostatic Theory of Gas Pressure.' He noticed that Professor Orton, himself, a short time before he died, expressed himself in a way as to indicate he was not altogether satisfied with his own theory.

Certain wells had been bored in New York that exhibited a pressure of 1500 pounds to the square inch. Professor Orton confessed that he was unable to suggest where the hydrostatic head sufficiently high to produce this pressure might be located; though in explaining the pressure in the Ohio and Indiana Trenton gas wells, he had gone as far as Wisconsin to get a head sufficient to explain pressures of approximately 450 pounds to the square inch. It has always seemed to the writer that Professor Orton's adduced argument here fell short of a demonstration. Even admitting that the Trenton rock is continuously porous under cover from Ohio and Indiana Gas Fields to outcrop 600 feet above sea-level in Wisconsin (a condition implicitly denied elsewhere, when he explains barrenness of Trenton rock in gas under area surrounding the 'gas belt' by the 'compactness of the rock'), it would still be necessary to suppose that the columns of 'Trenton brine' rising to 600 feet above sea-level in the wells, were balanced by a corresponding body of water of like specific gravity saturating rock up to the very limit of outcrop. Such an explanation calls for the saturation of Wisconsin surface Trenton with Ohio and Indiana Trenton brine. Further, it would appear that the argument is specious that would infer hydrostatic character of cause from similarity of 'observed' pressure in wells to that calculated for them from the height to which salt water rises in neighboring abandoned wells. Of course this would be so, no matter what the nature of the cause which produced the pressure. As well argue that the pressure of the atmosphere is 'hydrostatic' in origin, because it holds up a column of water a certain height between sucks in a pump.

In view of the objections above mentioned, may it not be necessary to revive the much derided theory of 'Rock pressure'—for which the term 'lithopiestic' is proposed? In the light of facts brought out in connection with the development of the petroleum industry in recent years, many of the objections urged against this theory no longer obtain. An examination of 'bituminous sandrock' from deposits which are nothing more than old petroliferous beds formerly deeply covered by overlying strata, but now exposed by denudation and with contents oxidized, shows that the bitumen takes the place of cement in other sandstones. In other words, it was accumulated before the rocks were consolidated, or (in accordance with the 'anticlinal theory') its accumulation accompanied their consolidation. In this condition the rocks were compressible, and with them their gaseous and fluid contents. Such compression could be the result both of weight of overlying rocks and lateral pressure—the latter the same which produced the anticlinal and synclinal folds permitting of a separation of the contents in accordance with their specific gravities. When a body of strata is thrown into gentle folds without fracture, some of the beds must almost certainly undergo compression. It would appear that a bed of bituminous shale, for instance, in contact with a bed of porous, but perhaps non-compressible, sandstone or limestone, would have some of its gaseous and fluid contents driven into the interstices of such rock and held there under pressure. Such pressure would become manifest whenever the rock was penetrated by the drill.

There are a number of phenomena connected with artesian and gas wells which are probably better in accord with the 'lithopiestic' than the 'hydrostatic' theory. One of these is the sensitiveness of pressure to tremors and movements of the earth.

One experiment suggests itself that would probably determine whether this pressure is in the main 'hydrostatic' or not. If all abandoned cased wells in a district can be filled up to the top of the casing or higher with surface water, which water will remain at that level, the pressure which held the original salt water to a certain level in the well could not be hydrostatic exclusively.

The contention here is not that none of the pressure is hydrostatic (doubtless water is mainly the medium through which it is communicated), but that for certain deep artesians and all high pressure gas wells the ultimate source of the pressure is mainly lithopiestic.

ARTHUR M. MILLER.

STATE COLLEGE OF KENTUCKY.

HEARING IN ANTS.

IN a recent number of SCIENCE (Nov. 24, 1899), LeRoy D. Weld describes some experiments upon a number of species of ants, demonstrating a sense of hearing. It may be of interest to record that in 1895 one of my students, Miss E. A. Wagner, who was keeping several species of ants under observation, found one species (not determined) of small black ant which gave unmistakable evidence of hearing. Miss Wagner's work was never completed, so that I can only give, from memory, an inadequate account of her results.

To most sounds this species, like the others studied, was apparently indifferent, and, so far as we could judge, insensible, but to a note of a certain pitch, whether sounded by a violin or by a whistle, the whole colony would react most vigorously, rushing about frantically, tumbling against one another, many of them falling into the water moat surrounding the nest, a thing they never did when undisturbed The appearance was that of extreme agitation. This response was obtained only to sounds of a certain pitch. On first sounding the note the ants which might be resting quietly in a compact group in the nest (asleep?) would apparently be startled to attention, standing tense with erect antennæ. A few of the outermost ants in the group would usually move about a little, but if the sound was not repeated they might return and all the individuals again become quiet. If the sound were repeated several times at intervals the agitation (?) would steadily increase until all the ants seemed fairly frantic, behaving in a way never observed under other circumstances. The reaction was equally decided whether the note was sounded near the nest or fifteen feet away at the opposite side of the room with the back turned to the nest. In only one species was any response observed, and in this species the response was only to a note of a certain pitch.

It is difficult to explain the violent reaction to only this particular note. What connection, if any, it may have with any features of the normal environment of these ants, I cannot suggest.

MAYNARD M. METCALF.
THE WOMANS COLLEGE OF BALTIMORE.

NOTES ON INORGANIC CHEMISTRY.

AFTER having been practically stationary for a number of years, the manufacture of sulfuric acid, which is the greatest of the chemical industries, has lately begun to make new and unforeseen advances. The first of these is the use of cast-iron vessels for concentration and is described by E. Hartmann in the *Chemiker Zeitung*. The great rise in the price of platinum has emphasized the necessity of some more economical material for concentration vessels, and it is found that, unless it is desired to have an acid absolutely free from iron, vessels of cast-iron can be used. The iron should be as free as possible from all impurities and as hard as possible. The acid is concentrated in lead pans to 61° *B*, then run into a small cast-iron vessel in which it reaches 63.5°–64° *B*, at a temperature of 180°. Finally it is run into two concentrating dishes in cascade arrangement, where a strength of 97% to 98% is obtained. The small vessel lasts three to four months and the concentrators from six months to over a year. The loss on wear of apparatus is however no greater than with platinum, and the first cost is insignificant in comparison.

THE second advance in sulfuric acid manufacture is nothing less than a complete revolution, and is described by Lunge in the *Journal* of the Society of Chemical Industry. It is the complete abolition of the lead chamber and towers, even of the use of nitrous fumes as oxygen carriers, and the use of the so-called catalytic power of platinum and other substances to occasion the union of sulfur dioxid and oxygen. In other words it is the utilization of an idea which has long been considered available for the preparation of sulfur trioxid and Nordhausen fuming acid. The Badische Anilin and Soda Fabrik has perfected this invention and is manufacturing its acid practically by this process and other firms are beginning to follow in its steps. Among the catalytic agents which have been used are pyrites, cinders. The principle feature of the Badische invention is the discovery that to obtain good results it is necessary to get rid of the heat of the reaction. With this it is possible to attain 98 per cent. of efficiency. The process is of course of greatest value for producing the strongest acid, and avoids especially any necessity for concentrating plants. For weaker acid, such as chamber acid, it is probable the old process will always be more economical. The new process has, however, the further advantage of giving an acid exceptionally pure and especially free from arsenic. This would seem at the present outlook to be the most important advance in technical chemistry in the last few years.

J. L. H.

*CAMBRIDGE UNIVERSITY**

A COMMENCEMENT has already been made with the new Geological Museum which will cost about £44,000, of which sum the fund raised as a memorial to Professor Sedgwick will supply £27,000. The contributions to the Benefaction Fund have made it possible to consider the erection of new buildings for Law, part of the funds for which will, it is understood, be contributed by the trustees of Miss Squire's will, for Medicine, Botany, Archæology and rooms for business purposes and examinations; but it is impossible to say until plans have been drawn and estimates made whether the resources of the University will allow of the erection of all these buildings at the present time.

Although the extreme pressure upon the funds of the University is thus removed and some of the most urgent of long-standing claims can be satisfied, the response made as yet to the Chancellor's appeal will not allow of any of the new developments of University work which many friends of the University consider opportune. In the interests of national progress it is greatly to be desired that laboratories of applied science should not be isolated, but should be established in connection with schools which are already strong in pure science. Technical training in any limited sense of the expression is impossible. In every subject of practical application, whether it be a learned profession or an industrial art, success depends upon breadth of knowledge of the sciences upon which the profession or art is based. Advances in technology are almost invariably due to the application by practical men of principles discovered by those who carry out investigations in pure science. Conversely the strength and vitality of the school of pure science is largely increased when opportunities are afforded to students of passing on to its applications.

The remarkable progress of Natural Science in Cambridge is closely associated with the growth of the Medical School. During the past twelve years a larger number of students have entered for the Natural Sciences Tripos than for any other examination for honors, notwithstanding the fact that but few students are in a position to allow their prospects in life to depend upon the discovery in themselves of a special aptitude for pure science. Almost all those who have since distinguished themselves in various branches of science have commenced their career by preparing to qualify for a profession. The majority of the graduates, for example, who are at present prosecuting researches in the physical, chemical, botanical, zoological, physiological, anatomical and pathological laboratories, making, to the great credit of the University, additions to knowledge which are not exceeded, if they are equalled in amount, by any other university in the world, entered as medical students. The phenomenal growth of the Engineering Department under Professor Ewing is also beginning to produce similar results; students who entered with the intention of becoming engineers have discovered in themselves a special aptitude for pure mathematics or for physics in one of its various branches. Thus experience shows that whereas there can be no doubt as to the advantages which a professional or technical department reaps from the support of a school strong in pure science, the advantages which pure science reaps from the proximity of departments of applied science are not less substantial. An examination of the class-lists, as well as the records of work done after graduation, shows with equal clearness that the older subjects of university culture do not suffer from the rivalry of new departments.

* From the report of the retiring Vice-Chancellor, Dr. Alexander Hill, Master of Downing College.

GRADUATE STUDY AND THE SMITHSONIAN INSTITUTION.

IT will be remembered that a committee representing the American Association of Agricultural Colleges and Experiment Stations requested the Smithsonian Institution to consider the organization of post-graduate study in Washington. The matter has been considered by a committee of the regents, consisting of ex-Senator Henderson, President W. L. Wilson, Professor A. Graham Bell, President James B. Angell and Representative Hill, which has drawn up a report that concludes as follows:

"The committee does not hesitate to express its warm and decided sympathy with the general purpose of the movement thus made by the associated colleges. The object sought commends itself to us all, and the zeal and ability with which it has been pressed upon our consideration by the very able and distinguished educators and scientists connected with these colleges furnish ample assurance that the consummation of the great and leading object sought by them is only a question of time. The material already collected in the bureaus and departments of the government furnishes a rich mine of the educational wealth that will not be permitted to remain forever undeveloped. This material is now being constantly enriched by the most valuable additions to its present enormous wealth. Already it has invited to the national capital many distinguished scientists, anxious to avail themselves of the superior advantages thus offered for investigation and research.

"Your committee, however, is painfully impressed with the fact that the powers of the Smithsonian Institution as at present organized are scarcely broad enough to embrace the work proposed. And the committee is equally impressed with the fact that even with enlarged authority its present financial condition would absolutely prevent anything like efficient and creditable performance of the work contemplated.

"It is well known to the members of this board that a great wealth of material—material which would be of immense utility in the successful accomplishment of the purposes indicated by the associated colleges—lies buried in the crypts and cellars of the National Museum.

"If our institution is unable for want of room, as it undoubtedly is, even to place this valuable material on exhibition for the public eyes, and as little to arrange it for scientific uses, the problem of providing halls for lectures and meeting the necessary expenditures incident to the work proposed becomes serious and formidable in the extreme. Your committee is not prepared to make definite recommendations to the board for its final or ultimate action. That which is clearly inexpedient to-day may become not only expedient but eminently desirable to-morrow."

THE MISSOURI BOTANICAL GARDEN.

FROM advance sheets of the administrative reports for 1899 of the Missouri Botanical Garden, it appears that as contrasted with the preceding year there was a slight increase in revenue, and that by a decree of the Supreme Court of the State of Missouri, affirming a decision of the lower court, handed down some years since, the Trustees of the Garden are now empowered to sell real estate originally inalienable, which, when improved, should sell for at least $1,500,000. The Garden expenses for the year were $32,174.36, in addition to which a small sum was spent on special improvements.

The Director's report shows that 71,021 visitors to the Garden were counted during the year, and that the collection of living plants, which included 8009 species and varieties at the beginning of the year, made a net gain of 1118, bringing the total at the end of the year up to 9127.

There were 32,890 sheets of specimens incorporated in the herbarium, which now comprises 340,350 sheets. The additions to the library comprise 642 books, 172 pamphlets, and 9042 cards, bringing the contents of the library at the end of the year up to 33,462 parts, of which 14,287 are books, and 19,175 pamphlets. The total value of the herbarium is now stated to be $51,052.52, and of the library $54,683.24.

It is stated that as a result of the recent decision of the Supreme Court touching the unimproved real estate constituting a part of the endowment of the Garden, the Trustees are now able to look forward to the gradual conversion of a large amount of unproductive, heavily taxed property into an income-producing form, while relieved from the need, which they have experienced during the past ten years, of withholding a large part of the current revenue annually for the protection of this property whenever the improvement of the streets through it should be ordered by the city. As a first step in the marked advance to be looked for, the Trustees have authorized the immediate grading of about twenty acres of ground adjoining the present Garden, according to plans prepared some years since by Olmsted, Olmsted & Eliot, the intention being to plant this area as a permanent addition to the grounds, in such a way as to add greatly to their attractiveness and to present in a compact form the leading features of the North American flora, which it is proposed to arrange essentially in the well-known botanical sequence of Bentham and Hooker; while some eighty acres adjoining are expected to be improved within a few years, in accordance with plans furnished by the same landscape architects, in such a manner as to represent as many as possible of the natural orders of plants, so arranged as to exemplify the more modern classification of Engler and Prantl.

SCIENTIFIC NOTES AND NEWS.

THE American Academy of Arts and Sciences has granted from the income of the Rumford fund $500 to Professor E. C. Pickering, for the purpose of carrying out an investigation on the brightness of faint stars by coöperation with certain observatories possessing large telescopes, and $100 to Professor T. W. Richards, in aid of a research on the transition points of crystallized salts.

COLONEL F. F. HILDER, of the Bureau of American Ethnology, has just been detailed as a special agent of the Government Board of the Pan-American Exposition, to visit the Philippines, for the purpose of making scientific and especially ethnologic collections. It is his plan to visit as many of the islands as practicable before the opening of the rainy season, and make collections illustrating the industries, modes of life and social conditions prevailing among both the wild and settled tribes.

MR. EDWARD G. GARDINER, Secretary of the Marine Biological Laboratory, accompanied by Mr. George M. Grey, Collector and Curator of the Supply Department, have left for Puerto Rico for a few week's tour along certain portions of the coast, with the intention of examining and making collections of the marine fauna. Mr. Gardiner expects to have the companionship and assistance of Admiral Grinell, retired, who is familiar with the language and mode of life in this island.

SIR MICHAEL FOSTER, professor of physiology in the University of Cambridge, one of the secretaries of the Royal Society and last year president of the British Association, has consented to become a candidate for the University of London's seat in Parliament, vacant by the elevation of Sir John Lubbock to the peerage.

THE Hon. Richard Olney has been appointed to the vacancy in the Board of Regents of the Smithsonian Institution caused by the death of D. P. Johnston.

DR. H. C. BOLTON has been elected president of the Chemical Society of Washington, and Mr. Whitman Cross president of the Geological Society of Washington.

PROFESSOR MILNE-EDWARDS has been elected vice-president of the Paris Academy of Sciences.

DR. F. FREIHERR VON RICHTHOFEN, professor of geography at Berlin, has been given the Bavarian Maximilian order for art and science.

DR. E. R. SCHNEIDER, professor of chemistry at Berlin, has been given an order of the crown on the occasion of the celebration of the fiftieth anniversary of his doctorate. The same order has been given to Dr. Felix Klein, professor of mathematics at Göttingen.

M. TH. RIBOT, professor of psychology of the Collège de France, has been elected to the chair of the Paris Academy of Moral Sciences made vacant by the death of M. Nourrisson.

PROFESSOR HENRY S. CARHART of the department of physics of the University of Michigan, who has been spending the year in Germany, is now in Zürich studying the subject of electrical engineering with Professor Weber.

PROFESSOR W. P. MASON, of the Rensselaer Polytechnic Institute, has gone te Europe to be absent until May.

THE president of the Local Government Board, London, has appointed Mr. William Henry Power, F.R.S., the assistant medical officer and medical inspector for general sanitary purposes of the Board, to the office of medical officer of the Board, in the room of the late Sir Richard Thorne Thorne, K.C.B. Dr. H. Franklin Parsons has been appointed assistant medical officer and medical inspector for general sanitary purposes, and Dr. R. Bruce Low has been appointed an assistant medical officer.

WE regret to record the death of Dr. John E. Davis, professor of mathematical physics in the University of Wisconsin.

WE regret also to record the death, on January 23d, of Professor Henry A. Hazen, one of the chief forecasters of the U. S. Weather Bureau at the age of 50 years. Mr. Hazen was killed as the result of a bicycle accident which occured the day before.

THE death of David Edward Hughes, F.R.S., is announced at the age of 60 years. He was the author of numerous papers on electricity and magnetism and the inventor of the Hughes printing telegraph instrument, of the microphone and of the induction balance. He had received the gold medal of the Royal Society and the Albert Medal of the Society of Arts.

THE death is also anounced of Mr. H. T. Coxwell at the age of 81 years. With Mr. Jamer Glaisher, F.R.S., he made in the early sixties a number of balloon ascents, including a noted one to a height of seven miles, which yielded important contributions to entomology.

THE following deaths have also occurred among men of science abroad: Dr. Karl Friedrich Rammelsberg, formerly professor of chemistry, in the University of Berlin, on December 29th, at the age of 86 years; Dr. Giovanni Zoia, professor of anatomy at Pavia, and M. Mather, the mineralogist, of Marseilles.

M. CAURO, assistant professor of physics at the Paris School of Pharmacy, has been killed while making experiments on Mt. Blanc on the interruption of the electric current through ice.

AT the meeting of the Academy of Natural Sciences, of Philadelphia, on December 26th, a life-size portrait of Linnaeus was presented to the Academy by Mr. Charles E. Smith. It is a copy by Mr. Boude-Wijnse of the original portrait belonging to Baron Verschuer at present in his country house near Haarlem. In an interesting letter read before the Academy, Mr. Smith states that he had been searching for the portrait for about 20 years, and explains how he had overcome the difficulties in finding the picture and securing the copy.

THE Torrey Botanical Club has appointed a committee to prepare a program in commemoration of the life and work of Dr. John Torrey, to be presented before Section G, of the American Association for the Advancement of Science, at its meeting in New York, in the last week of June, 1900.

THE will of Ex-Chief Justice, Chas. P. Daly, made, it appears, in addition to the public bequests already noted, a bequest of $20,000 to the New York Botanical Garden, payable on the death of his wife's sister. The Garden also receives one-twelfth of the residual estate.

MR. and Mrs. Samuel M. Nickerson have given to the Art Institute of Chicago, their entire art collection, said to be the most valuable private collection of ivories and rare oriental carvings in Chicago, and the second in value in the United States.

THE annual meeting of the Board of Regents of the Smithsonian Institution was held at Washington on January 24th. The report of Secretary Langley for the year ending June 30, 1899, was presented and accepted.

THE House Committee on Agriculture has authorized a favorable report on the bill to reorganize the Weather Bureau, the chief provisions of which were described in a recent issue of this JOURNAL.

THE New York Botanical Garden announces among recent accessions, a gift of 25 microscopes from Mr. W. E. Dodge, to be used as part of the permanent display in the Museum; the greater part of the botanical library of the late Dr. Hossack; a herbarium, containing many valuable specimens, from Mr. John J. Crook; 200 drawings made by the late Professor August

Koehler, and plants from Mr. H. P. Kelsey and Mr. Nathaniel Thayer.

M. MAURICE LÉVY, in assuming the Presidency of the Paris Academy of Sciences, in January 2d, made two requests, as follows: "La première, que nous commencions toujours nos séances à l'heure réglementaire; ce sera d'autant plus expédient cette année que le public comprendra souvent des étrangers, envers lesquels, citoyens d'une République, nous devrons observer cette vertu des rois: l'exactitude; la seconde, qu'au cours de nos séances, notre attention, qui est toujours très grande, veuille bien toujours se montrer aussi silencieuse qu'elle est grande.

IT is stated that Herr Vaze, the German Polar explorer will lead an expedition into the Arctic regions next summer in the hope of finding traces of Andrée.

ON the 20th of February Mr. A. P. Low of the Geological Survey of Canada, who has explored the Labrador Peninsula during the past eight years and only recently returned from an eighteen months' sojourn in that once but little-known land, will deliver a lecture upon the Labrador Peninsula under the auspices of the Ottawa Field-Naturalists' Club in the Academic Hall of Ottawa University. The lecture will be illustrated with lantern slides.

IT is reported that the Navy Department and the Lighthouse Board of the Treasury Department have declined to accept the terms offered by Mr. Marconi's representative, and will make experiments with a view to developing an independent method of wireless telegraphy.

THE Fifth Section of the International Congress of Comparative History to be held at Paris during the Exposition is a congress on the history of science. The *British Medical Journal* states that the object of the promoters is to bring together persons interested in the study of the history of the various sciences, and to prove to them that it will be to their common advantage to work together, so as to render the study of original documents easier. The Organizing Committee, of which M. Paul Tannery is president, has drawn up a long list of subjects which are considered to be ripe for discussion. Proposals for schemes for encouraging the study of the history of science are also invited. The Congress will have an independent organization and will be held from July 23d to July 28th. The official language will be French, though papers in German, English or Italian will be received. Further information can be obtained from Dr. Sicard de Plauzoles, Rue St. Dominique 124, Paris. Among the committee are Professor Paul Berger, Prince Roland Bonaparte, Professor Brissaud, Professor Hahn, the Prince of Monaco, Prince Henri d'Orleans, Dr. Pozzi, and Professor Charles Richet.

THE London *Times* states that at the meeting of the British Astronomical Association, on December 27th, Mr. Maunder made a statement with reference to the arrangements that are being made for the proposed expedition to Spain and Algeria, to view the solar eclipse of May 28, 1900. He said that, subject to a sufficient number of passages being actually taken before January 31st, the Royal Mail steamer *Tagus* or a sister vessel would be engaged, and would start from Southampton on Friday, May 18th, at 6 p.m., calling at Cadiz and Alicante, and arriving at Algiers at 6 a.m., on Thursday, the 24th. The vessel would stay there until after the eclipse, leaving at 6 a.m., on Tuesday, the 29th, and calling at Alicante, Gibraltar, and Lisbon on the way to Southampton, which would be reached at 7 a.m., on Monday, June 4th. It was hoped the members of the Association would divide themselves into three groups—those observing the eclipse (1) in the interior of Spain: (2) at Alicante or neighborhood, and (3) in Algeria, where the ship would act as hotel for those who might wish to use it in that capacity. The first party would, it was expected, break up into two chief sections—those who would alight at Cadiz and rejoin the ship at Alicante, and those who would rejoin the ship at Gibraltar. The entire party would thus have the opportunity of visiting Gibraltar and Lisbon. The latter port, however, would only be visited in case it was quite free from plague infection. In case a sufficiently large party should wish to alight at Cadiz and visit the chief cities of Southern Spain, arrangements would be made with Messrs. T. Cook and Sons for tours to Seville, Cordoba, Granada, and other places of interest. All these arrangements, however, would fall through unless a sufficient number of passages had been definitely engaged before January 31st.

AT a recent meeting of the British Departmental Committee on preservative matters in food, Professor A. Wynter Blythe testified according to the *London Times*, that formerly it was quite rare to find aniline dyes in food, the simpler forms of colors, such as cochineal and burnt sugar, being used, but latterly it was quite rare to find natural colors. The rule and not the exception now was to use so-called tar colors. Dye was not largely used in coloring wine, as the grape gave it a sufficiently nice color. In no substance, however, which he had examined would the quantity of aniline dye, even supposing it to be poisonous, be enough to injure health; but having regard to the many things colored in this way, it was a question whether the collective amount which a child, say, might take in a day might not have some injurious effect. The great majority of these dyes were not poisonous. Injurious, as distinct from harmless, colors should be scheduled. There would be little difficulty in prohibiting aniline dyes and in detecting a breach of the prohibition. Such a prohibition would be useful, and the drawing up of the schedule would be easy for some central authority, say the Local Government Board, or the Board of Agriculture. It should be made the duty of the vendor to declare the presence of coloring matter. As to boracic acid in milk, he did not approve of treating an almost universal article of food with a drug, unknown to the consumer, but it would be very difficult to forbid it altogether in, say, London, where the bulk of the milk came from the country, and where much would be spoilt unless a preservative were used. Here also the presence of the preservative should be notified. Salicylic acid was not much used except in temperance drinks to arrest alcoholic fermentation. Mr. Richard Bannister, Fellow of the Institute of Chemists and of the Chemical Society, and late Deputy-Principal of the Inland Revenue branch of the Government Laboratory, said bacon was at present brought into England with the aid of borax; it would not be possible to bring it over in refrigerators, as was done with fresh meat, except at a great increase of cost, and even then it would not be in exactly the same condition as at present, or equally fit for the English market. Both in the bacon and butter trade he considered preservatives a necessity. There would be no objection to making it obligatory on the vendor of milk to notify the presence of a preservative, but there would be difficulty in stating the amount, because it was difficult to estimate its amount. Salicylic acid was chiefly used in British wines and liquids which were presented in a clear form, and in which there was not a sufficient quantity of alcohol to make them clear and bright.

UNIVERSITY AND EDUCATIONAL NEWS.

PRESIDENT SCHURMAN has announced an anonymous gift of $80,000 for Cornell University to erect a building for physiology and anatomy.

BY a decision of the New York Court of Appeal, Yale will receive the $150,000 bequeathed by William Lampson.

PRESIDENT BASHFORD of the Ohio Wesleyan University announces that Mrs. Elizabeth Mebarry of Richmond, Ind., who recently gave $50,000 to the university, has added $10,000 to the fund, thus endowing two chairs.

A COURSE in landscape architecture to extend through four years has been arranged by the Lawrence Scientific School of Harvard University.

THE trustees of the University of Cincinnati have declared vacant nine of the twelve professorships, and one of the remaining three professors has since resigned. The instructors and assistants also retire.

MR. S. T. DUTTON, Superintendent of Schools in Brookline, Mass, has been elected professor of school administration in Teachers College, Columbia University.

THE *American Geologist* states that Mr. A. G. Leonard has charge of the geological work at the University of Missouri in the absence of Professor Marbut.

MSS. intended for publication and books, etc., intended for review should be sent to the responsible editor, Professor, J. McKeen Cattell, Garrison-on-Hudson, N. Y.

*ON THE ABSORPTION OF CONDENSATION-PRODUCING ATMOSPHERIC DUST BY SOLID NUCLEI AND SURFACES, AND ON THE DIFFUSION VELOCITY OF SUPPOSEDLY NON-IONIZED DUST PARTICLES.**

LET r be the radius of a tube stretched along the axis X, and conveying dust-laden air at a velocity, v. Consider two sections at a distance dx apart; the dust entering per second at the near face is $\pi r^2 nv$; the dust leaving per second at the rear face is $\pi r^2(n + [dn/dx]dx)v$, if the air current is kept constant and n is the density of dust distribution, or is proportional to the number of particles per cubic centim. On the other hand, the absorption of dust particles by the walls of the section in question, is $k \cdot 2\pi r \cdot n \cdot dx$, where k is the absorption per square centim. per second, per unit of dust concentration, and the absorption, as a first hypothesis, is taken proportional to the density of distribution of particles in air.† Hence $-\pi r^2(dn/dx)dx \cdot v = k \cdot 2\pi r \cdot n \cdot dx$,

or $$\frac{dn}{n} = -\frac{2k}{vr}dx. \qquad (1)$$

Let the density in case of air saturated

* Preliminary report of work made with a grant of the Smithsonian Institution, and published by permission of the Secretary.

† Briefly k is the diffusion velocity of the dust particle, *i. e.*, its normal velocity in air at rest. Equation (1) neglects the spontaneous dissipation of dust particles. This is permissible for the fast air currents v of Table I. The full equation is treated below.

with dust be taken as one. To determine the constant of integration it is to be observed that when $x=0$, or $k=0$, there is no absorption; but the current of air must nevertheless be kept up passing either through the absorption tube or not, to retain a colored field in the color tube. Now saturated dusty air would be objectionable seeing that an opaque field is produced unsuitable for measurement. Hence even when $x=0$, or $k=0$, the influx current is unsaturated, and we may suppose this minimum current to be obtained through a fixed initial length of tubing, x_0, of the same kind. Thus the tube virtually begins at $-x_0$, and equation (1) becomes on integration

$$n=e^{-\frac{2k(x+x_0)}{rv}}. \qquad (2)$$

If the observations be so made that the dust density issuing from the length x of tubing is constant, we have for a given color tube, $n=n'$ and

$$\frac{x+x_0}{v}=\frac{x'+x_0}{v'}. \qquad (3)$$

For different tubes under the same conditions,

$$k/k'=\frac{vr}{x+x_0}\Big/\frac{v'r'}{x'+x_0}.$$

Hence, ignoring the undeterminable constant, one may write briefly

$$2k=vr/(x+x_0). \qquad (4)$$

With this preliminary theory as a point of departure, I have been making an extended series of observations on the condensation of supersaturated steam obtained from jets, and following the general method of color tubes described in my memoir * on the subject published by the U. S. Weather Bureau in 1895. By passing measured quantities of air (V litres per minute), saturated with the emanation of phosphorus, through different lengths of absorption tubing,* and regulating the air current by a graduated stop-cock till a definite color (full blue) appears in the field of the color tube, the condition $n=$ constant is fulfilled, on provision that no change has occurred in the action of the tube during the interval. As V is the influx of dusty air per minute, $1000v/60=\pi r^2\cdot v$, and as $2k=vr/(x+x_0)$,

$$k=\frac{2{\cdot}65}{r}\cdot\frac{V}{x+x_0},$$

where $V/(x+x_0)$ is given by the observations of volume in terms of length of absorption tube for a fixed blue in the field of the color tube. If V_0 be the minimum volume, *i. e.*, the influx volume of dusty air corresponding to $x=0$, $k=2.65/r\cdot V_0/x_0$; hence, finally,

$$k=\frac{2{\cdot}65}{r}\,\frac{V-V_0}{x}. \qquad (5)$$

Aside from the difficulty of observing subject to color criteria, equation (3) is well borne out by the data obtained, to the extent that V is a linear function of x. V_0, however, does not always coincide with observation, and a certain additional tube length must in certain cases be added to compensate for the dissipation (eddies?) encountered on entering the absorption tube. But this is non-essential.

A brief summary of the present results is given in the following table, which shows the material of the absorption tubes, their diameter, the variations of length (x) and volume (V) occurring in each series of experiments (usually 10 or 20 in number). The pressure under which steam issues from the jet is shown under p (centims. of mercury), and the temperature (°C.) of the air flowing into the color tube, under θ. Within reasonable limits, discussed elsewhere, the color tube is not sensitive to

* A Report on the Condensation of Atmospheric Moisture; Bulletin, No. 12, pp. 104, U. S. Weather Bureau, Washington, 1895.

* Ordinary tubing used for absorption purposes, *i. e.*, to catch the dust particles moving laterally out of the dust-laden air current.

either of these variations. The table also gives the ranges of the velocities of dust-laden air through the absorption tubes resulting from the differences of length, and the limit of values computed for k showing the errors of measurement. The final column contains the mean value of k obtained from the data as a whole.

to be seen whether greater refinements of method* will rather bring the k-values to coincide for all condensing surfaces or accentuate differences.

At all events, it is already clear that the velocity of the phosphoric dust particle is independent of its density of distribution.

In the Bulletin cited, the work of which was done in 1893, and elsewhere,† I denied that colored cloudy condensation was ever due to ions, a theory then rife and particularly discussed by the younger v. Helmholtz, Bidwell and others. None of these investigators have, to my thinking, made out a clear case. Since the advent of the X-rays and of the brilliant work done at the Cavendish Laboratory, however, the status of the question has changed materially. Nevertheless I am still loth to abandon my former conviction that condensation is always primarily due to nuclei; and that whether they are ionized or not (none were certainly known until recently), is a matter of secondary and perhaps negligible consequence. Thus for instance, concentrated sulphuric acid is a dust producer comparable to phosphorus; and yet this is the very reagent that has always been used in drying the chambers of apparatus when high insulation is specially wanted. Certainly one would be rash to thrust the wily ion in such a chamber. Indeed the interest which attaches to the above results is this,

TABLE.—ABSORPTION OF PHOSPHORIC DUST* IN TUBES.

Tube of	Diameter.	Range of Lengths, x	p	θ	Range of V†	Range of v‡	Range of k	Mean k
Gray rubber	.64cm.	0–455cm.	4cm.	26°	.7–7.0	40–360	.08–.12	.123
Pure rubber	.35 "	0–300 "	6 "	24°	.5–4.2	80–740	.12–.16	.137
Lead	.63 "	0–300 "	5 "	27°	.5–4.6	30–250	.15–.18	.162
Lead	.32 "	0–150 "	9 "	27°	.7–2.0	140–410	......	.160
Glass	.29 "	0–150 "	8 "	27°	.8–2.0	200–480	......	132

In view of the widely different values of the velocity with which the dust laden air traversed the absorption tubes, the high velocities employed and the marked difference of material which makes up the absorbing walls, the close proximity of the values of k is particularly noteworthy when the meaning of this constant is called to mind: k being the absorption per square centim. per second per unit density of distribution, is simply proportional to the velocity of diffusion of the phosphorus emanation, or in other words, to the velocity with which the particles ejected from phosphorus by an oxygen reaction travel normally through the surrounding air. In the cases of glass, of impure vulcanized gray rubber, of pure brown rubber, this velocity is so far as observation warrants, the same. In the case of lead tubes the velocity set forth by k is slightly larger, a circumstance which may have an electrical or a chemical bearing, or be referable to the greater density of these tubes. It is entirely premature to speculate upon it. It remains

*Similar results were obtained with dust particles ejected by concentrated sulphuric acid.

† Litres per minute.

‡ Centims. per second.

*The color estimates in the table were made by the eye. It will not be difficult to repeat them relative to some fixed standard blue.

† *Nature*, XLIX., p. 363, 1894.

that strong evidence is afforded in favor of a specific velocity of the particles of a supposedly non-ionized dust, so far as the phosphorous emanation has been known. Since they are always absorbed they must clearly soon vanish out of any vessel, usually within five minutes if considered in bulk. A large part of this dissipation is referable to the grosser dust particles in ordinary air.* Thus if phosphoric dust and a suitable small quantity of smoke of ammonium chloride (made in the usual way) be passed into the color tube, the field which is opaque with phosphoric dust alone, becomes cleared when the sal-ammonium smoke is added. The larger particles of the latter have therefore captured the finer particles of the former (phosphorus emanation); and as sal-ammonium smoke alone, if not itself opaque, is unable to produce colored cloudy condensation or opacity, the field clears at once. Now if sal-ammonium smoke can capture phosphoric dust then it is conceivable that agencies may exist which reverse the fortunes of war and liberate phosphoric dust. Heat is such an agency. If nearly effete dust be passed through a hot tube (say above 400°), experiment showed me that the condensation producing tendency is again restored, precisely as if the dust were dissociable. At a higher temperature still, though not necessarily above red heat, the tube itself becomes an energetic dust producer at its inner walls, even when of glass so that experiments of the present kind are delicate. Indeed long ago I asserted that the strong dust producing activity of flames was a conversion of coarsely disseminated into finely disseminated atmospheric dust, a conversion of the planets of this microcosm into nebulæ, as it were.

One may readily conceive the X-rays to be another such agency. After some trials I devised a form of apparatus appropriate for my purposes, by which the condensational tendency of air energized by X-rays,* shows almost as powerfully in the color tube as does the older dust laden air. So far as the effect of these different kinds of dust on the color field is concerned, one would be unable to distinguish any noteworthy difference of behavior. Both may be carried through tin tubes 2 inches in diameter and over 60 feet long, taking one or more minutes in the transfer, without encountering fatal diminution in the condensation producing power of either. Other and now well known experiments of an entirely different nature go to show that X-ray dust is ionized, or transferred in a region of ionized gas, whereas the ordinary dust, with which I have chiefly worked, is not; but I ask, if both classes of dust are under proper limitations, equally able to induce condensation in supersaturated aqueous vapor, how can one single out the exceptional quality of ionization as the cause of this tendency? It has been brilliantly proved by J. J. Thomson, Rutherford, Chattock, and indirectly by C. F. R. Wilson, that ionized dust has a definite velocity; but in as far as the above experiments have weight, so has the supposedly non-ionized dust.

* This secondary dissipation is neglected in the differential equation (1), being of much smaller order than the surface effect investigated. With the wide tubes (diameter 2 inches), presently to be mentioned, the differential equation replacing (1) above is

$$-\pi r^2 v\, dn/dx = kn2\pi r + k'n^2/v$$

where k' is the number vanishing per second per unit of concentration of dust in air. The last term decreases as v, the velocity of the air current increases. This equation is easily reduced as a case of Riccati's equation, and the integration may therefore be made without difficulty.

* Of course, the X-ray tube must be boxed up most carefully, the rays shining through an aluminum window, and the terminals imbedded in paraffine. Any highly potentialized conductor, like a hot body, is apt to dust the air.

One way of escaping between the horns of the dilemma is to suppose the ionization to exist even when not directly evidenced. Thus most of the dust with which I have worked is derived by oxidation, or by heat implying chemical action or dissociation, or from highly potentialized matter, etc. Phosphoric dust is quite inactive at low temperatures and in a current of air free coal gas. The same is true of molten sulphur. Concentrated sulphuric acid, however, shows increased activity when a current of coal gas is passed through it into the color tube; but the action here is probably a destruction of the coarse dust particles in air, the effect being similar to that referred to in the case of flames. Facing the question squarely it seems extremely difficult to account for a specific velocity in the non-ionized dust particle. Being already stupefied in observing that a much larger volume of air of initially constant dust content must be discharged through a wide tube than through a narrow tube of the same material, and within certain limits of diameter, instanced by the above table, one may well be daunted in confronting the case of a specific velocity in an inert dust particle.

The need of a direct decision is, therefore, urgent; is this phosphoric dust ionized or not; or better, is it generated in an ionized region? Using an electroscope, which in the dry room in which I worked retained its charge indefinitely, I aspirated a current of air across the charged terminal without appreciable result. I then blew air which was passed over phosphorus across the terminal, and found to my surprise that even with a small current the charge was dissipated more than one-half in the first minute. It made no difference whether a positive or a negative charge was on the electroscope. Hence, phosphorus, when emitting condensation-producing dust seems also to emit some form of obscure radiation; for the dust evolution* occurs in a strongly ionized region, or the dust is itself ionized. Relative to the experiments of the above table, therefore, fresh means are at hand for computing the velocity of the phosphoric dust particle, and the electricity carried per gram, in a way similar to the famous researches made at the Cavendish Laboratory, independently of the preceding results. This suggests one method of standardizing the colors of my color tube, absolutely in terms of the number of dust particles per cubic centim. producing the color effect.

With the question thus happily answered in the case of phosphorus, I next examined air passed over concentrated sulphuric acid, but found it without effect even on the electrometer. Though the acid is a weaker dust producer than phosphorus, the present electrical result seems out of proportion to the data of the color tube. The decision made is therefore partial, but I have not advanced beyond it. Other dust producers might be instanced in the same category, and it is for this reason that I have retained the antiquated designation 'dust' in this paper.

I may add that in the experiments which I have under way, I have been dealing somewhat extensively with questions of the above nature, using dust either ionized or not. My methods, however, are all restricted to an application of the steam jet,

* I shall show elsewhere, and have since verified experimentally, that if air energized by phosphoric dust be maintained between the plates of an air condenser, the difference of potential, ϕ, vanishes according to the equation

$$\phi = \phi_0 \, \varepsilon^{-nket}$$

in the lapse of time t, where e is the charge per particle. For different thicknesses, d, of air, the decay of energized dust particles in successive layers of air is very similar to the absorption of light in successive thicknesses of medium, viz., $n = n_0 10^{-\alpha d}$. In my experiments I found $a = .25$, and thus the number of particles is reduced to 1/10 in a layer of air 4 centimeters thick.

since this is an instrument with which I am familiar, and since this mode of attack has not at all been cultivated by the recent investigators on allied questions. The steam jet method has undoubtedly many grave shortcomings; but it has one invaluable advantage of retaining a given color of field for an indefinite interval of time, so long as the conditions of action are left unchanged. My present work has shown me, moreover, that the complicated character of the evidence derived from the jet, is much less serious than I have hitherto supposed. Among the inquiries with which I have been much occupied, is a determination of the number of particles which give rise to a given colored condensation in the field of the color tube, contributing to an optic phenomenon of exceptional interest, the theory of which is as yet quite unknown. Should this phenomenon yield to treatment, there would be given, since there is no serious difficulty in finding the collective mass of the particles, an independent method, and one not depending on electrical agency, of ascertaining both the individual velocity and possibly the mass of these subtle and pervasive dust particles, absolutely. For let m_0 and m be the masses of dust absorbed per square centim. per second in the first and final sections of the absorption tube. Then $n = m / m_0$ and the velocity k in equation (2) is thus the only unknown quantity.

CARL BARUS.

BROWN UNIVERSITY.

RECENT OUTLOOKS UPON MUSIC.

THE field of music is too vast to be seen from any single standpoint. The ignoring of this simple truth has led to countless misrepresentations of facts by writers, and misunderstandings of books by readers. For tacitly it is assumed by most of us that there is only one standpoint, indefinitely thought of as that of the modern musical performer or intelligent concert-goer; and if we do recall that some mathematicians praise another point of view, while Greek, Oriental and mediæval musicians apparently had others, we yet know they have been too rarely visited to have much influence on musical thinking.

But the discoveries of the last few years bearing on the questions of the basis of music and the historical development of scales have rendered it possible for the student of comparative music to occupy a point from which many long-known facts appear entirely changed, and older authorities, as Fétis, Helmholtz and Ambros, are seen to be inadequate, if not erroneous. In comparison with this standpoint, that of the modern musician appears to be a rapidly shifting one, like an observation car or the masthead of a ship.

It is the purpose of this paper to review from this new-found standpoint some parts of four rather recent books* of more than temporary interest and value, that deal with various parts of the field; and by their aid to define the musicians' standpoint, and indicate some of the problems now before the student of the history and basis of music.

I.

Klauser's book was the first in order of publication, yet is probably the least known of the four. From title page to conclusion it bristles with novel ideas, developed during, and verified, he asserts, by many years experience in teaching. The hearty pub-

* 'The Septonate and the Centralization of the Tonal System,' by Julius Klauser. Milwaukee, 1890, pp. vi + 274; 'The Art of Music,' by C. Hubert H. Parry. New York, 1893, pp. 374; (The new English edition has the title, The Evolution of the Art of Music); 'Primitive Music,' by Richard Wallaschek. London, 1893, pp. 326–9; 'A Study of Omaha Indian Music,' by Alice C. Fletcher; with a report on the 'Structural Peculiarities of the Music,' by John Comfort Fillmore, A.M. Peabody Museum, Cambridge, Mass., 1893, pp. vi + 152.

lished commendations of such music teachers and writers as W. S. B. Matthews and C. B. Cady, of Chicago, may justify one in feeling that it is more than the work of a dreamer or idle rhapsodist,—that what he has observed of the operations of his own mind in hearing music, can be observed in other minds also.

The introduction is a vigorous plea for 'a higher education in music,' with a severe indictment of ordinary methods for their ignoring sound pedagogical principles. "The *how* is studied before the *what*:" the order should be reversed. "The musician is represented in the *what*, the instrumentalist in the *how*: the two must be combined in one individual. There is a far more important instrument than the voice, piano, organ or violin, whose technique must be developed to a high degree of automatism. This instrument is the mind" (p. 25). "The ready-made tone of the piano is a serious though not an insurmountable obstacle to the development of the mental instrument of the pianist. By the employment of logical methods, the piano is best suited as an auxiliary to a higher musical education" (p. 26). "I have already stated that the mental automatism requisite to a discriminating musician is very great. When an able musician listens to or reads a piece of music, he hears and comprehends all its melodic, rhythmic and harmonic incidents as fast as they take place in a given *tempo*. This means that he listens to music just as he would listen to any familiar tongue. * * * To stop to think is the sure sign that we do not understand" (p. 29). "I have demonstrated in my capacity as teacher that children may be intelligent musicians from the start" (p. 32). "But such results * * * are made practicable only by the simplification of the Tonal system itself. * * * The child requires a simpler foundation than the scale to begin on. The scale-half or tetrachord and the septonate supply this desideratum" (p. 33).

Then follows his novel way of looking at tones and their relations. The first chapter is mainly devoted to definitions; the tones of any series are felt to be either 'reposetones' ('harmonics') or 'progression-tones' ('by-tones'), the latter lying a step or half-step under or over the former (p. 40). A tone is nothing definite until it is relationed in a key, that is, thought and heard in relation with a tonic, which is the point of absolute repose (p. 41). The Tonic is a CENTRAL tone or klang, and the remaining key-klangs are equally distributed *over* and *under* it (p. 42). The seven tones of the scale arranged with the tonic in the center form a *septonate*, composed of two tetrachords or *scale-halves*, an over and an under one: thus,

G—a—b ◡ C—d—e ◡ F.

A key-group contains these seven principals, also five up-mediates (the sharp-notes) and five down-mediates (the flat-notes), or seventeen in all, including five more sharps and five more flats; a full tone-stratum consists of twenty-seven tones; so there are only twenty-seven tonic centers, and only twenty-seven keys in music. Every key has two modes, a bright or major, and a dark or minor mode (p. 51).

In the second chapter it is suggested that "whether we will or not we cannot think a series of tones, even in one voice, except in connection with some harmony," though this is not necessarily conscious (p. 54), and then the attempt is made to prove that the accent determines whether a tone is felt to be a harmonic or a by-tone, and so accent determines harmony (p. 71).

Chapters three and four continue the analysis of tone relations and intervals; there is space only for two points: in a rising scale-half as G to C, the tones may be called Dominant, Passing By-tone, Leading-tone, and Tonic (p. 78): And second, the student should begin with counterpoint and get his earliest intelligence of harmony therefrom (p. 117); for all through attention is directed, not to harmony, but to one governing voice (p. 167).

Chapter five deals with Harmony and six with Suspensions, Inter-relations of keys and Modulation. The boldness of the author's thought about tone-relations appears in such passages as these: "It is plain that any tone and any combination may be relationed in any key. What the presiding key of the moment is, and when a change of key takes place, are matters that are determined by the melo-rhythmo-harmonic inter-relations in which a series of tones appears" (p. 221). "Modulation takes place (even in one voice) at the very moment a shift of relation to another key-center takes place" (p. 253).

The final paragraph is curious: "Since there are twenty-six keys to modulate into from any one key, and twenty-seven ways from one key into each of the others, there are $26 \times 27 = 702$ ways out of and into any one key," and "$27 \times 702 = 18{,}954$ ways in which a prominent voice can modulate" (p. 265).

So much for a meagre presentation of the author's views. While there are many quotable passages in his book, it is strikingly free from quotation, and the very few references to other writers are general, not specific. He objects to Dr. Riemann's theory that major and minor are polar opposites (p. 96), and feels that Helmholtz's explanations are inadequate (p. 270), on which points the reviewer agrees with him. As an offset to his serious discussion he gives a page on nature-music which is more fantastic than Gardner's book of sixty years ago. The student of comparative music notices with interest how this most modern exponent of music interpretation and of music psychology throws away notions of the scale that have been laboriously and fruitfully developed during the last 800 years, to take up the old Greek heptatonic system of two conjunct tetrachords, with *Mese* in the central position, though his are Lydian instead of the usual Dorian tetrachords. And one notices further that by limiting the series to seven tones which are repeated in successive tone-strata, this new system is brought into correspondence with more than one Oriental system; for except among Europeans the eighth note is not usually counted as belonging with the seven, but it starts a new series, and in one case is called by the happy name 'response.'

II.

The reader of Dr. Parry's book feels at once that he is under a master. The author has the degree of Doctor of Music from Oxford, Cambridge and Dublin; he is well-known as one of the leading English composers, and a number of years ago contributed to Grove's Dictionary of Music most of the articles relating to the theory of music: so he was admirably equipped by knowledge of the past, experience as a composer, and maturity of judgment to analyze the musical impulses and expressions of men and to put the results of such analysis into fitting words. Probably no book ever written is so well adapted as this to help the non-musical reader to some understanding and appreciation, both of what music is as an expression of the human soul, and of the artistic means employed in this expression. So far as can be done by one book it brings music back to where the Greeks placed it, to the position of a liberal art, of an instrument of culture as truly as poetry or history or painting; it makes musical training mean something quite other than an accomplishment, or the ability to perform or enjoy a performance, or acquaintance with the history of musicians and their works, or even the power to analyze a musical composition in the usual way. And all his wealth of information and inspiration is poured forth in a clear stream, in language precise and often felicitous, so that one may turn these pages with pleasure even for the style alone.

The earlier chapters throw some light on the subjects covered by the other books under review, and the extracts must be limited to passages bearing on these subjects. In the chapter on Preliminaries, it is pointed out that the intensity of men's pleasures or interest leads to expression; this to be intelligible requires common terms, that is, a design. Design is the equivalent of organization in the ordinary affairs of life. In music especially, form as well as design is necessary, but this book has only to do with design. Music is the expression of what is in man and, therefore, is not mainly imitative. "The story of music has been that of a slow building up and extension of artistic means of formulating utterances which in their raw state are direct expressions of feeling and sensibility." Everywhere are voices, shouts, etc., "but neither music nor speech begins till something definite appears in the texture of its material; some intellectual process must be brought to bear upon both to make them capable of being retained in the mind" (p. 5). "It was not till mankind had arrived at an advanced stage of intellectuality that men began to take note of the relations of notes to one another at all" (p. 6).

"The first indispensable requirement of music is a series of notes which stand in some recognizable relation to one another in respect of pitch" (p. 16). Then follows a thirty page account of the scales used in various parts of the world, which is quite satisfactory, being based mainly on the work of Ellis and Hipkins. While the author avoids the common error of assuming that these were attempts to obtain our scale, he has been misled in some cases by the dogmatism of some of his authorities, as in treating of the Persian-Arabian scale; and he has not got so far away from the modern musician's position as to observe more than what other people have done; their principles and their reasons have escaped him. His "summary is sufficient to show the marvellous variety of scales developed by different nations for purely melodic purposes" (p. 44). Of our scale he says the functions of the notes (dominant, mediant, etc.), are always being expanded and identified with fresh manipulations of the principles of design by able composers: the classification of these functions puts our harmonic scale eight centuries ahead of all melodic systems; and the last stage in this development was the assimilation of all the keys to one another by equal temperament.

In the chapter on Folk-Music, it is pointed out that orderliness and intelligibility in tunes proceed parallel with the general development of capacities in a race. It is very difficult to make out what intervals savages intend to utter. The elements of design that appear among them are repetition, perhaps at different levels, and sometimes the contrast of two short phrases. Tonality marks a considerable advance, and the impression of finality depends on this. The resources of art are not sufficient to allow a long consistent development of a single movement in melodic art; so Orientals fall back on ornament; this is "the part of anything which makes for superficial effect; * * * it generally implies either undeveloped mental powers or great excess of dexterity." In modern German folk-music the harmonic basis is simple and obvious. As art-music grows, folk-music tends to go out of use; for civilization reduces everything to a common level.

From this point on the author treats

only of European music. Harmony came in to help out the church music which was slow and free from marked rhythmic effect. The beginning of harmony is due to the fact that men's voices were of different calibre; only intervals of a fourth and fifth could well be tolerated in simultaneous singing, and so the parts were doubled at these intervals; there is no reason for thinking that this was offensive, as it would be to us. "This doubling does not imply a sense for harmony" (p. 95). Slowly there came in a recognition of the value of different consonances, of discords and of interruptions of the voices. This chapter unfortunately does not recognize the important part taken by the organ in the development of harmonic ideas; the Chinese have had slow sacred music and voices of different calibre for thousands of years, but have no harmony: the organ we believe was the instrument that brought about the development.

In the following chapters Pure Choral Music, Secular Music, Instrumental Music, The Sonata-Form, and Opera are traced from their beginning, with constant reference to the aims and methods of the great composers, and to their share either in enlarging the resources of design or giving expression to human feeling. The temptation to quote at length is very strong. One passage (somewhat condensed) from the chapter on Modern Tendencies will give an idea of the manner of treatment: Palestrina without emotion embodies the most perfect presentation of contemplative religious devotion. Bach * * * formulates a more liberal and energetic type of religious sentiment, and foreshadows by his new combination of rhythm and polyphony the musical expression of every sort of human feeling. Beethoven expresses the complete emancipation of human emotion and mind, and attempts to give expression to every kind of inner sensibility which is capable and worthy of being brought into the circuit of an artistic scheme of design. * * * The love of art for art's sake is at best a love of beauty for itself. * * * This is inevitable at one stage; but humanity as it grows older instinctively feels that the adoration of mere beauty is sometimes childish and sometimes thoroughly unwholesome; and men want to be sure that the human energies are not sapped by art instead of being fostered by it. After both beauty and expression have reached a high plane men seek for strong characterization, as in all the arts to-day, and especially in literature.

Finally, one more quotation somewhat condensed may be commended to the careful study of all who attempt to interpret the music of strange peoples in terms of European music. "Wagner's harmony is the result of polyphony in great measure; he does not abandon tonality, but uses it with quite remarkable skill and perception of its functions; in accompaniment of the ordinary dialogue he is often very obscure in tonality, just as J. S. Bach is in recitative. For straightforward ideas he uses simple diatonic figures; for something specially mysterious, chords which belong to two or more unassimilable tonalities on purpose to create the sense of bewilderment, and a kind of dizziness and helplessness which exactly meets the requirements of the case. If people's sense of tonality were not by this time so highly developed such passages would be merely hideous gibberish, and they often seem so at first" (p. 356).

III.

Wallaschek's book on 'Primitive Music' takes us from the most extreme modern position to the consideration of the beginnings and rude early manifestations of the musical art. The first fifth of it is devoted to a collection of explorer's reports on savage music, little reference being made to peoples who have developed a musical theory, as the Arabs and Hindus. The materials for this chapter have been collected from a wide field, and the reviewer can bear witness to the thoroughness of the search, as he had previously gone over a large part of the ground.

In the following nine chapters much of this matter, with some additions, is arranged under these heads: Singers and Composers; Instruments; the Basis of our Musical System; Physical and Psychical Influence of Music; Text and Music; Dance and Music; Primitive Drama and Pantomime; The Origin of Music; Heredity and Development. Then follows a full Bibliography, an Index and 25 melodies. The author's standpoint is that of a psychologist, as is evident from his papers in *Mind* and in German journals; so he seems most at home in the later chapters.

It is unfortunately true that few of the travellers whose reports are quoted showed any particular fitness to speak on musical questions, or especially to write down correctly as to rhythm and melody the songs they may have heard; so the reports must be used by the student with great care and discrimination. The author's uncritical treatment of his material may be judged from this passage: "In Virginia (North America) for instance, several rattles are tuned together, and the natives have 'bass tenor, counter-tenor, alto and soprano rattles'" (p. 103). On looking for the authority for this statement, made as if true for to-day, one finds it at the end of the book John Smith's History of Virginia; but the date of publication (1624) is nowhere given. Another passage will throw light on the author's judgment of what facts are important and characteristic: After referring to musical contests for endurance among savages he says: "Barbarian as it may appear to be such performances are still in use in America, the modern counterpart being the 'musical' contest which took place at Huber's Museum, New York, on the twenty-third of October, 1892"; the lady played the piano 16 hours 52 min., her competitor, a man, 17 hours; she received five proposals of marriage (p. 72)! Must we confess that America is not entitled to the barbaric preëminence tendered her, for the *London Musical Times* tells of a man who played the piano in public for twenty-five hours consecutively, again for thirty-six hours, and again for forty hours.

In connection with the present review, Chapter IV. is of most interest, for in it are presented the similarities between savage music and ours; the matter is arranged under the three heads of: (1) Harmony, (2) Major and Minor Key, (3) The Scale. Much is made of the facts that various reporters tell of savages singing in two or several parts; the Hottentots especially are said to have keen ears, to be able to give excellent imitations of German hymns after once hearing them, and to employ harmony. The author concludes, "thus neither harmony nor the germs of counterpoint are entirely unknown to primitive nations, and it would seem from all the examples that I was able to collect that the principle of tonality is in most cases unmistakable" (p. 142). It cannot too positively be declared that such a statement is misleading, and in the sense that most readers will understand it, is utterly false; the musical dictionaries give six meanings for the word 'harmony'; it is only by using the word in a very loose and unusual way that it can be applied to the simultaneous singing of any savages yet reported; the use of the terms counter-point and tonality is equally loose.

In the next part comes the statement "it is surprising how often savages sing in the minor key" (p. 145); then various instances are noted of minor music though the ideas are merry and vivacious. "This occurrence of minor chords in savage music is no doubt of the greatest importance and will have to be taken into consideration in further researches on the physiology and psychology of music. * * * It is questionable whether savages notice any peculiar difference." As historically our minor came late into use, "we may connect with it the idea of the unusual, and may use it on occasions when something extraordinary is intended" (p. 149)! There is no need of quoting more, for the author knocks the foundation out from under his philosophical structure when he says, "it is also the uncertainty of intonation and the constant fluctuation of the voice which give us the impression of the minor key rather than of the major." One might as well say that the uncertainty of articulation of a savage speaking in his own tongue gives the impression of say cockney English, rather than English as spoken in Boston. Later we shall return to this matter of the interpretation of the sounds one hears.

The last part of Chapter IV., on the scale, is chiefly notable for the author's repeated assertion that the diatonic scale has been the constant basis in the development of music; for his clear-cut statement that the scale cannot be founded entirely on any natural properties of the ear or laws of the constitution of musical sound; and for his insistence on the instrumental origin of scales. The first of these three points is demonstrably inadequate and untrue; the others we believe to be true and important, though often ignored or denied.

In view of the great dearth of books covering this field it is but slight praise to call this decidedly the best one in the market. Some of its defects have already been pointed out; the author is from the nature of the case compelled to build with such materials as other men bring him; some are of excellent quality, some are rubbish; there is, therefore, unusual need for a careful critical treatment of them. But all students of the subject will welcome his collection of material, and the bibliography and many suggestive passages, though they will hardly be willing to cite his conclusions as authoritative.

IV.

Miss Fletcher's monograph is by far the fullest and most carefully-made collection of savage music of which we have any knowledge. Her discriminating remarks on the difficulties of observing and recording what was sung may be commended to those who, like the author of the preceding book, seem to think any statement of a traveller is good evidence, or that it is an easy matter to note down characteristic music. This collection is the fruit of ten years of study, including many years of life among the Omahas: it is therefore written from an intimate knowledge of the life of the people; throughout it impresses the reader with the feeling that it is a remarkably sympathetic work; that never did an author enter more fully into the thoughts and feelings of an alien race. For this is far more than a collection of carefully noted tunes, difficult and admirable as such a work would be; there are added the meaning of the song to the people who use it, and the circumstances in which it is used, so that the reader may appreciate it somewhat as the native does.

The melodies thus collected were put into the hands of the late Professor Fillmore for study. He sums up the results of a laborious and interesting investigation thus: "The deficiencies and defects of Indian music are, first, lack of sensuous beauty of tone-quality; second, uncertainty of intonation. * * * The merits of the Indian music consist, first, in an elaborate, well-developed rhythm; second, in fresh, original, clear, characteristic expression of the whole range of emotional experience of a primitive people. * * * The problems presented in the study of primitive music are two : 1. The problem of the origin and function of music ; 2. The problem of the psychological, physical and acoustic laws in accordance with which the musical phenomena have become what they are" (p. 74).

The most novel part of Professor Fillmore's work is that dealing with the question of harmony in savage music. It has long been customary to add a harmony to simple melodies of people who never use accompaniments; and as many as thirty years ago Carl Engel showed the great danger of distorting the meaning of a tune by this procedure. But the author takes an almost opposite position, and maintains it with vigor; he holds in substance that the meaning of these songs cannot truthfully be presented without harmonizing them; certainly their interest is greatly increased, as no one can doubt who has had the privilege of hearing them rendered by the authors of this book and their coadjutor Mr. La Flesche; so rendered, some of them are very fine and inspiring and moving. In adding the harmony Professor Fillmore has taken the unusual precaution of submitting every piece of music to native judgment, and out of several modes of harmonization has selected that one which pleased Indian hearers best. As a result of this long testing, he concludes that the matter of scales to which ordinarily so much attention is given, is entirely subordinate; that any peculiar scale can easily be accounted for on harmonic grounds; and that the tonality is to be decided "not alone from the tones actually employed in the song, but from considering what tone or tones need to be supplied in order to make a natural or satisfactory harmony" (p. 64). Above all he thinks he has proved the existence of a 'latent harmonic sense' unconsciously determining the choice of melody-tones, or as stated in another place, "It seems clear to me that the course of these melodies can be accounted for in no other way than on the assumption that the Indian possesses the same sense of a tonic chord and its attendant related harmonies that we do: although of course it is latent and never comes clearly forward into his consciousness" (p. 76). But in spite of this positiveness of conviction there is a suggestive doubt expressed in the last paragraph; "how the feeling for the tonic chord is generated in melodies which do not begin with the key-note, and especially in those which begin with a by-tone, as some of these songs do, I am as yet unable to conjecture" (p. 77).

These views of the joint authors have received hearty (though not universal) acceptance in musical circles, but ethnologists and other students of the problem of savage music dissent from them. To make clear the fundamental reason of this dissent, it will be necessary to go back and recall some things that the other books under review help to establish. To do this is important; for it is the reviewer's firm conviction that no one thing so hinders the intelligent study of non-European music as the wide prevalence of views similar to, though less clear and well developed, than those of which Mr. Fillmore is so able a defender.

And first it is to be recognized that all these authors have much in common, and, however divergent their outlooks, occupy substantially the standpoint of the modern European musician: so, collectively, they help to make more evident than a single book does just what this standpoint is. Klauser declares and Parry implies, as quotations from both have shown, that music is not a physical, but a psychological product, that most of its meaning anywhere is due to habituation, to long familiarity with the elements out of which it is built up; that it is conventional, in the same sense that spoken language is conventional. The listening musician is constantly trying to find the composer's meaning in a passage always imperfectly rendered; so he is being constantly trained to correct instinctively the sounds heard so as to fit them into his scale; then more or less consciously he notes the inter-relations of the sounds, the key and mode, modulations, rhythm, etc., for if these elementary things are obscure, the musical thought must be still more so; the case is closely parallel with the understanding of a spoken discourse. All this training and more is implied in the term 'musician.' Klauser's purpose is to promote such training and make the student conscious of it: Parry throughout implies that it is the basis of musical intelligence, and sometimes recognizes it rather explicitly: Wallaschek shows something of it: Fillmore and Miss Fletcher are saturated with it.

Now when a musician thus trained hears foreign music he cannot ordinarily help treating it in the familiar way, and assuming both that his notation is suitable, and that his familiar ideas are applicable. He reads into it his own notions and disregards what seems foreign to his established system. The students of savage and oriental languages have passed through and beyond this stage of development; so to-day the laity as well as scholars know that the utmost facility in and appreciation of one's mother tongue confer no ability to spell the words or understand the meaning of a foreign language; why then should a high musical training be thought *per se* to confer the ability to understand the music of a foreign race? We constantly hear that 'music is a universal language,' but the usual criticisms on foreign music or expressions of disgust with it show that the saying is substantially false, and that the words of a learned Chinaman to Amiot a century ago are far truer: "The airs," he said, "of our music go from the ear to the heart, and from the heart to the soul; we know them, we understand them; those that you play for us have not this effect." Fortunately a few writers have at least recognized that such terms as major and minor, modulation, tonality and harmony have very rarely, if ever, any applicability to foreign music; for instance, Mr. Parry does so in a passage in Grove's Dictionary, holding that these terms do not apply to anything inherent in this non-harmonic music, but only to the effects produced by it on hearers with European training.

It is just here, over the interpretation of the sounds heard, or the choice of a standpoint from which non-European music shall be judged, that the conflict is sharpest and most irreconcilable between professed musicians and the few scientific students of comparative music. Of the writers under review Parry has little and Klauser has nothing to indicate that there is a conflict, but they define admirably the advanced musician's standpoint; the others dealing exclusively with non-harmonic music should recognize the conflict and justify their choice of a standpoint if they would be accepted as authorities. But neither Wallaschek nor those from whom he quotes have, except rarely, made even the slightest attempt to find any other standpoint; while Fillmore repeatedly, triumphantly, and with italics declares that there is no other, saying for instance, "These melodic aberrations to which I have referred are easily and naturally accounted for by reference to their natural harmonic relations, *and in no other way*" (p. 61). His able paper is practically a challenge to every scientific student of musical problems; one must accept it and fight to victory in his own mind, or give up the contest for the application of scientific methods of research; for in effect it denies that the methods which have revolutionized the study of the history of religion, society, language and art, can be applied to music. Moreover, if Mr. Fillmore's presentation is correct it is hard to avoid the conclusion that the Omahas, though unconscious of it, are at the same stage of musical culture as he was; for he was just able to account for every peculiarity of their music, but only by bringing in "pretty much the whole ground of modern harmonic structure," including "the use of the third and sixth relationships in harmony, one of the most notable peculiarities of the Modern Romantic school" (p. 62). One cannot resist the suspicion that the writer has portrayed a cloud-land, not real hills lying as distant from his point of view as savagery is from civilization,—a suspicion strengthened by a multitude of facts, that there is no space here even to hint at.

But lest this criticism be misunderstood let us remind ourselves that in reporting music, as in writing history or producing a picture, there are two distinct ways of working; one aims either at a photographic, literal, scientific, analytical presentation, or at an artistic one; rarely at both. If the worker's aim be not regarded his most successful portraiture may be considered false; the artist disregards details, aiming rather at the impression of the whole; the scientific worker must first have the details. Miss Fletcher presented her "collection of Omaha Indian songs feeling confident that therein is truthfully set forth in a manner intelligible to members of my own race the Indian's mode of expressing emotion in musical forms" (p. 7): so her aim was artistic; she deliberately disregarded the material she had collected along the lines of physical or scientific presentation. She does not pretend to give the Indian music accurately as to pitch or quality, but in a translation, as it were, or perhaps rather a paraphrase. Many persons can deny that she gives Indian music; probably she is the most competent witness on the question whether her melodies with Mr. Fillmore's harmonies express to white musicians the emotions of the Omahas. No one doubts that for Miss Fletcher's purpose the modern musician's standpoint is the necessary one: is there any more doubt that for Mr. Fillmore's philosophical and scientific purpose it is absolutely unfit, and that views from it are obscure and misleading?

V.

While all such faithful, sympathetic attempts to paraphrase foreign music are cordially welcomed, we must not forget that an even harder work remains to be done:—to find out the elements of every strange musical language, and the rules by which they have been combined, and so to come to some real understanding of the thoughts and moods that lie back of the musical expression. In spite of the brilliant successes of the present generation in making vivid before us the life and thoughts of past generations, the story of the world's music has not yet been told; and the thousands of unsatisfying pages that attempt to do it still leave the subject in the condition of Egyptian history before the hieroglyphs were deciphered. The strong light thrown by the books under review on the position of modern European musicians shows that they are even farther removed from musicians of all other lands and times, than any one realized a few years ago. So before an author can write an adequate universal history of music, he must find, and occupy at least for a time, some other standpoint than that occupied by the writers of these books.

Charles K. Wead.

THE EFFECT OF THE MEXICAN EARTHQUAKE OF JANUARY 19, AT MOUNT HAMILTON, CALIFORNIA.

The detection of the occurrence of a distant earthquake shock, by means of a Meridian Circle, appears to be sufficiently novel to be worthy of record. The effect was noticed here, upon setting the telescope for the Nadir observation, on the night of Friday, January 19th, the date of the earthquake, most seriously felt at Colima, Mexico.

The reflected images of the threads were at once seen to be swinging across the field of vision, with a regular oscillation, much like the swing of a pendulum. The period was about seven seconds for the full amplitude of the swing. The extent of the arc could be exactly estimated, in the east and west direction, by the fixed transit threads, and appeared to be of the same amount in the north and south direction. The reflection from the surface of mercury doubles the actual angle of inclination, which was very closely 15″, for the full arc of vibration, at the maximum seen.

This corresponds to a total displacement of the eye end of the telescope of $\frac{1}{200}$ of an inch. A movement of twice this amount in the surface of the earth, when produced suddenly, will ordinarily be detected as a slight earthquake shock, and will be recorded by delicate seismographs. It would fall at II. of the Rossi-Forel scale, and is about as slight a vibration as can usually be detected. The delicacy of this test is shown by the fact of the oscillations being still easily perceptible when they had fallen to less than one-tenth of the above maximum.

It is probable that vibrations in the earth's crust of much larger extent would still be entirely imperceptible to the senses when taking place as slowly as in the present case. They are believed to extend to great distances from the active center of the disturbance, at least in special cases; and may perhaps precede the sensible shock by a considerable interval. In the additional instance, recorded below, there is little doubt that the early vibration was the forerunner of an earthquake shock, which was local only, as far as known.

In the present case, if the same vibrations extended to the summit of our large dome, they would amount to but the twentieth of an inch in actual displacement; and being of so slow a period, no injury would be anticipated. We have records here of displacements of the earth's crust during earthquake shocks of twenty times that of January 19th, coming as sharp and continued vibrations.

The oscillations were first noted at 10h. 50m. Pacific standard time, eight hours slow of Greenwich. Local time would be six minutes less. They continued of the same amplitude, apparently, for five minutes at least, and at 11h. 5m. had diminished to about one-quarter of the maximum. At 11h. 15m. they were still easily perceptible, but appeared no longer as uniform; the reflected image would appear stationary for several seconds and then continue the swing.

At 11h. 30m. the vibration had so nearly ceased that the Nadir observation was made, in order to determine whether any change had taken place in the position of the instrument. The comparisons with preceding and following determinations indicate no change in any particular. The swing was nearly as regular as a pendulum at the beginning, and there was little variation in successive swings, except as they diminished in intensity, just as a pendulum comes to rest.

The night was at that time nearly calm; the wind, which had been earlier light from the northwest, having died out. It should be added that the Nadir observation is usually easily made here. There are no shocks to be anticipated of any character at night, and the wind, even at 40 miles an hour, does not interrupt the reflection of the images. When coming in strong gusts there is no vibration at the surface, either coming from direct pressure or carried down by the walls of the building. The last will often quiver and rebound from the impact of the wind, as if it had been hurled against us in solid form. There is, of course, some difficulty in obtaining a steady illuminating flame during high winds, but no disturbance of the mercury surface.

The last previous observation of a star had been made upon a circumpolar at upper culmination, and nothing unusual was noticed up to the time of leaving the telescope. The last thread was taken nine minutes before the oscillation was detected at the Nadir, or at 10h. 41m. P. S. T. In the interval the circles and micrometer were read and the meteorological record taken for refraction. The barometer was again read, shortly following the cessation of the disturbance, and no change had taken place. The automatic recording instrument does not indicate any disturbance in the pressure during this interval.

The probable error of a telescope bisection is not greater than the hundredth part of the oscillation, at the maximum; so that it is clear that nothing of that nature was occurring at the time of observation. Nor could it fail to be detected in the transit record.

The circular reading, itself, might not indicate the beginning of the vibration; since it was of so slow and regular a character, that the telescope would probably have not been disturbed, in its position upon the pivots. An earthquake shock usually changes the position of the telescope in the wyes; in one case a change of 3″ was noted, as effect of a small, but perceptible tremor.

There is, thus, no way in which to fix the commencement of the oscillation, between the limits of 10 h. 41 m. and 10 h. 50 m. The duration is extraordinary, especially considering its minute amount. It was continuously observed for forty minutes. So impressive and startling was its character, when noted in an instrument of such stable form of mounting, that the observer had no hesitation in announcing the coming of an earthquake for this locality. Some previous experience served as the basis for such a prediction. On May 7, 1894, a similar oscillation, but far less pronounced in extent and duration, was detected by the same means. It was followed, after an interval of an hour and five minutes, by a slight earthquake, noted by three observers on Mt. Hamilton.*

In observing from two to three hundred nadirs a year, these two instances are the only ones noted of any vibration in the mountain. The indications were that this presaged a shock of a serious nature; and the chagrin, for an unfulfilled prophecy, is easily more than counterbalanced by the relief from the experience of a severe earthquake.

The connection with the Mexican earthquake is pretty clear, taking into account the slightly detailed accounts that have yet reached us. That was most severe at Colima, and Guadalajara, six or seven persons having been killed, many injured, and much damage to old and substantial buildings having been done. The first accounts of that disaster reached us on Monday, through the daily papers; and it appears that no further details are likely to be printed in that form. At Colima, the time was given at a quarter before twelve. At Guadalajara it was recorded at midnight. These cities are 18°, or a little more than an hour east of Mt. Hamilton: so that the first statement of the time would make the epoch near the beginning of the vibration noted here. Until more exact details of the times, recorded in Mexico, are known here, it will not be possible to check for closer agreement.

The cities where the worst of the shock

*Pub. Astr. Soc. Pac., 1894, Vol. VI., p. 184. Catalogue of Earthquakes, E. S. Holden: Smithsonian Miscell. Collec., No. 1087, p. 227.

was felt, are distant 1500 miles from this point. The shock would appear to have reached IX. of the R. F. scale, at the center. It will be interesting to learn how far this side the center, any sensations were noticed. The delicate indications of a fine telescope, poised over the mercury, will fill in the gap between the borders of the sensible shock, and the far extent of the real disturbance of the earth's crust.

R. H. TUCKER.

LICK OBSERVATORY, UNIVERSITY OF CALIFORNIA,
Jan. 24, 1900.

NOTE.—The thirty-six-inch and twelve-inch refractors and the Crossley reflector were in use while the oscillations of the earth, recorded by Professor Tucker, were taking place, but no unusual disturbances of these instruments were noticed. The observers were not, however, aware of the disturbance of the mercury under the meridian circle.

J. E. K.

THE CHICAGO SECTION OF THE AMERICAN MATHEMATICAL SOCIETY.

THE Section held its sixth semi-annual meeting at the University of Chicago on Thursday and Friday, December 28 and 29, 1899. Four sessions, two on each day, were fully occupied with the presentation and discussion of papers. Professor Moore, Vice-President of the Society, occupied the chair during the first session, after which Professor E. W. Davis presided.

The following papers were read:

(1) MR. R. E. MORITZ, University of Nebraska: 'A generalization of the process of differentiation.'

(2) PROFESSOR E. D. ROE, Elmira, N. Y.: 'On the transcendental form of the resultant.'

(3) DR. E. J. WILCZYNSKI, University of California: 'An application of Lie's theory to hydrodynamics.'

(4) DR. F. R. MOULTON, University of Chicago: (1) On the question of the stability of certain particular solutions of the problem of four bodies; (2) Particular solutions of the problem of n bodies of the Lagrangian type.

(5) PROFESSOR L. E. DICKSON, University of Texas: 'The canonical form of linear homogeneous substitutions in a general Galois field; (2) The cyclic sub-group of the simple group of linear fractional substitutions of determinant unity in two non-homogeneous variables with coefficients in an arbitrary Galois field.

(6) DR. J. V. WESTFALL, University of Iowa: 'On a category of transformation groups in space of four dimensions.'

(7) PROFESSOR O. BOLZA, University of Chicago: 'The elliptic sigma-functions considered as a special case of the hyperelliptic sigma-functions.

(8) PROFESSOR ALEXANDER PELL, University of South Dakota: Calculation of the integral

$$\int e^{-\left(px^2+\frac{q}{x^2}\right)} \begin{matrix}\sin\\ \cos\end{matrix} \left\{rx^2+\frac{s}{x^2}\right\} dx.$$

(6) PROFESSOR JOHN A. MILLER, Indiana University: 'Concerning certain elliptic modular functions of square rank.'

(10) PROFESSOR ROBERT J. ALEY, Indiana University: 'A new collinear set of three points connected with the triangle.'

(11) PROFESSOR H. MASCHKE, University of Chicago: 'Note on the unilateral surface of Moebius.'

(12) PROFESSOR C. A. WALDO, Purdue University: 'On a family of warped surfaces connected by a simple functional relation.'

(13) PROFESSOR HENRY S. WHITE, Northwestern University: 'Plane cubics and irrational covariant cubics.'

After the papers listed above had been read there followed a general discussion on the topic 'Limits of function of one or more variables' introduced by Professor Moore.

The program committee for the following year was elected at this meeting and will consist of the Secretary *ex-officio*, Professor H. B. Newson, University of Kansas, and Professor C. A. Waldo, Purdue University.

The next meeting of the Section will be held on Saturday, April 14, 1900, at Northwestern University, Evanston.

THOMAS F. HOLGATE,
Secretary of the Section.

EVANSTON, ILLINOIS.
Jan. 6, 1900.

*CORDILLERAN SECTION OF THE GEOLOGICAL SOCIETY OF AMERICA.**

A YEAR ago, as has been already reported in SCIENCE, about a dozen west coast geologists met at Berkeley and organized the Cordilleran Geological Club. The organization was at once recognized as temporary, and the project of organizing permanently as a Section of the Geological Society of America formed a leading topic of discussion at the meeting. The following spring a number of fellows of the Society resident in California memorialized the Council of the Society, setting forth their inability to be present at the meeting of the Society owing to the great distance at which they reside from the usual places of meeting, and praying for legislation on the part of the Society which would enable them to meet as a geographically distinct Section of the Society. The Section was formally recognized by the Society at its Washington meeting, and the Council of the Society was authorized to frame rules governing the Section in its relations to the main Society.

The meeting of the Cordilleran Section was very successful, and it is clear that its organization will greatly strengthen the Society in the West. Provisionally Professor Joseph Le Conte was elected Chairman, Andrew C. Lawson, Secretary, and Professor J. E. Talmage, Councilor, the three to constitute an executive committee.

The following papers were presented :

The discovery of a goat antelope in the cave fauna of Pike's Peak region. By F. W. CRAGIN, Colorado Springs, Colo.

In having the cave-earth removed from a cave in the Manitou limestone of his Glen Eyrie estate a few years since, General W. J. Palmer saved organic remains, consisting of a number of bones, and submitted them to the writer for determination. Two of the specimens belonged to a slender-limbed horse of the late Pliocene or Quaternary age. Other remains belong to a species of woodchuck, probably different from any now living in North America. A humerus and cannion bone of a two-toed ungulate were found to differ from the corresponding bones of all the artiodactyles now living in North America, but agreed closely with those of the Capricorn or Goat-Antelope (*Nemorhœdus*) of the Himalayan region. In recognition of General Palmer's liberal patronage of science the species is named *N. palmeri*.

The finding of goat antelopes in the extinct fauna of the Rocky Mountains, though unexpected, is no more remarkable than the occurrence of elephants, which are also of Oriental origin.

On the occurrence of ground-sloths in the Quaternary of Middle California. By JOHN C. MERRIAM, Berkeley.

The remains of two ground-sloths have recently been obtained from Middle Californian deposits of unquestioned Quaternary age. The first specimens found consisted of large humerus fragments obtained by Judge Jones, of Martinez, Calif., on the south shore of Suisun Bay. Associated with them were remains of *Elephas* and a large species of *Equus*. During the past year, 1899, Mr. A. Huff obtained a large and perfectly preserved humerus from loose, horizontally stratified deposits on the eastern shore of Tomales Bay, in Marin County, Calif. An *Elephas* tooth seems to have been obtained from the same deposit.

The specimens from the two localities seem to belong to the same or closely related species. This form fits most satisfactorily into Marsh's genus *Morotherium*, which was described from material obtained in Alameda County, Calif.

Classification of the John Day beds. By JOHN C. MERRIAM, Berkeley.

The John Day beds average about fif-

* First annual meeting, San Francisco, Calif., December 29 and 30, 1899.

teen hundred feet in thickness, and apparently contain a very large proportion of volcanic materials. They seem to rest unconformably on a thick series of plant bearing, fresh water beds, which have been considered Eocene. The Columbian lavas rest apparently unconformably upon the John Day beds.

On the basis of lithologic and stratigraphic characters, the John Day System may be divided into three divisions, lower, middle, and upper John Day. The lower beds are mainly colored a brilliant red, seem to have suffered more disturbance than the higher beds and are practically barren of fossils. The middle beds are blue, green or drab, and are in in places quite fossiliferous. The upper beds are bluff or white. They are largely made up of volcanic material. Many fossils have been obtained from this division. One horizon particularly is rich in rodent remains.

The writer's study of the vertical range of the John Day species has not progressed far enough to permit of any definite statement regarding their zonal arrangement. Professor J. L. Wortman has already proposed the division of the system, on faünal grounds, into upper *Merycochaerüs* and lower *Diceratheriüm* beds. The use of the lithologic divisions here proposed will greatly aid in the study of the vertical range or history of John Day species.

Notes concerning erosion forms and exposures in the deserts of South Central Utah. By J. E. TALMAGE, Salt Lake City, Utah.

A description of the effects of denudation in the region lying east and south of the Thousand Lake Mountain, and west of the water pocket fold. The dissection of the Trias and Jura was illustrated by numerous photographs. In the work of rock disintegration much importance was attached to the great diurnal range of temperature, the range being 80° to 85° F. during the autumn months. Dykes and hills are prominently exposed in certain parts of the region. Selenite geodes similar to that first reported in SCIENCE, February 17, 1893, are of frequent occurrence.

On certain peculiar markings on sandstones from the vicinity of Elen Cañon, Arizona. By J. E. TALMAGE, Salt Lake City, Utah.

The paper was illustrated by photographs and slabs of the rock. The markings appear as right lines with approximately rectangular intersections; the lines are shallow troughs from .5 mm. to 2 mm. in width though occasionally in coarser rocks they are as much as 9 mm. wide and 3 mm. deep. The rectangles have an average size of about 4x6 mm. Unbroken lines of 395 cm. have been traced. The rock is a fine-formed argillaceous sandstone of brick red to chocolate color. It occurs as a bed two feet thick between coarser sandstones. Ripple marks, rain drop impressions and sun cracks appear in the marked rock.

Attempts to reproduce the right line markings were described, leading to the conclusion that the lines are perhaps the result of crystalline cleavages in saline cakes deposited through desiccation. Pinate impressions suggesting frost flower pictures occur with the right line markings and these were reproduced experimentally. Slabs of the stone $2\frac{1}{2}$ square yards in size and completely covered with the right lines were taken from the deposit.

Conglomerate 'puddings' from the Paria River, Utah. By J. E. TALMAGE, Salt Lake City, Utah.

The paper was an explanation of photographs, showing a number of fresh conglomerate masses, consisting of pebbles and mud formed by accretion through rolling. The formation of these puddings was observed on the mud flats of the Paria. The sticky mud and river, worn pebbles readily cohere, and by rolling the lumps, increase in size and were found ranging in size from three inches to two feet in diameter. When left to dry they fall to pieces. Some were observed partly buried in the mud; and it is probable that many have been covered up by flood deposits.

Thomsonite and other zeolites from Golden, Colorado. By HORACE B. PATTON, Golden, Colo.

The points of interest are remarkably beautiful and delicate masses of Thomsonite recently found, and the extraordinary variety in habit of this material in the same and closely adjacent cavities. The paper was accompanied by photographs.

The peneplain question upon the Pacific Coast. By H. W. FAIRBANKS, Berkeley, Calif.

A topographic study of the islands of Southern California. By W. S. TANGIER SMITH, Berkeley, Calif. Presented by Andrew C. Lawson.

The islands are classified according to their general physiographic features, and the main reasons for the pronounced differences found are given. The physiography of each island is then considered in some detail, and a general description of the submarine features of the coast of California (particularly in the south) is also given. This is followed by a consideration of the chief conditions governing the formation and preservation of terraces and other wave-formed features. Finally, the most recent movements of the coast are considered, with the conclusion that the islands have moved in unison with the mainland.

An early geological excursion. By JOSEPH LE CONTE, Berkeley, Calif.

An informal narrative of a camping trip in 1844 to Lake Superior, thence up the St. Louis river, thence by portage into the upper tributaries of the Mississippi, thence down that river to Fort Snelling, thence by steamer to Galena, St. Louis, and Pittsburg, and finally by rail back to New York. The paper was of interest chiefly from a historical point of view. For example: The writer went to Lake Superior with the first mining party (Colonel Gratiot's) that opened the Lake Superior copper mines and camped with the party for three weeks at Eagle Harbor. After leaving Eagle Harbor on a canoe trip of about 800 miles, only three or four white men were seen. The canoe was drawn up on the very spots where Duluth and Minneapolis now stand, but many years before those cities existed. Many important geological observations were made and recorded for the first time, but the writer was too young to appreciate their full significance.

Some coast migrations, Southern California. By BAILEY WILLIS, Washington, D. C.

The sequence of events discussed in the paper includes (1) the development of the Santa Lucia series; (2) erosion of the Santa Lucia series; (3) deposition of the Franciscan conglomerate, sandstone and shale; (4) orogenic movements which resulted in profound deformation of the Franciscan formations; (5) deep erosion of the Santa Lucia and Franciscan rocks, which is partly represented in later sediments; (6) evolution of the present mountain system and coastal front. The paper presents observations made during a trip from Monterey to San Luis Obispo along the intervening coast ranges. The writer was accompanied by Dr. H. W. Fairbanks, in whose articles many of the facts presented have already been published.

The sandstone reefs of Brazil. By J. C. BRANNER, Stanford University.

The geological significance of soil study. By E. W. HILGARD, Berkeley, Calif.

This paper discusses, first, the importance and convenience of observations on soil areas and their characteristic vegetation, in the delineation of geological formations. It then treats of the chemico-geological relations between the latest geological formations, soils, and the more ancient deposits which, after emergence, have been subject to subaërial agencies.

The American Devonian placoderms. By E. W. Claypole, Pasadena, Calif.

Following a detailed discussion of the structure and relationships of the principal Devonian genera of North American placoderms, the author presented his views on the habits, habitat, origin and migrations of the great armor-clad forms.

The Berkeley Hills—a detail of Coast Range geology. By Andrew C. Lawson, Berkeley, Calif.

A discussion of the geological history and structure of the hills in the vicinity of Berkeley, accompanied by a colored map on a scale of 1 : 12,000 and six geological sections.

Andrew C. Lawson,
Secretary.

---

*PROFESSOR HENRY ALLEN HAZEN.**

By a sad accident on the evening of Monday, January 22d, the Weather Bureau lost one of its most prominent officials. Professor Henry Allen Hazen, while riding rapidly on his bicycle, hastening to his night work at the Weather Bureau, collided with a pedestrian and was dashed to the ground. After lying unconscious for twenty-four hours, he expired on the 23d. His body is interred in the family burying-ground at Deerfield, Massachusetts.

Professor Hazen was born, January 12, 1849, in Sirur, India (about 100 miles east of Bombay), the son of Reverend Allen Hazen, a missionary of the Congregational Church. He came to this country when ten years old and was educated at St. Johnsbury, Vermont, and at Dartmouth College, where he was graduated in 1871. After this, he removed to New Haven and was for four years instructor in drawing in the Sheffield Scientific School, and for four years subsequent was assistant in meteorology and physics under Professor Elias Loomis. He was also privately associated with the latter in meteorological researches and the preparation of many of the 'Contributions to Meteorology,' published by Professor Loomis, some of which bear evidence of the reflex influence of the student on the master.

In the spring of 1881, when the present writer first saw Professor Hazen in New Haven, the latter showed such an earnest interest in meteorology as to justify recommending him to the position of computer in the 'Study Room' which was then being organized by General William B. Hazen the Chief Signal Officer, for the purpose of developing the scientific work of the Bureau, as a necessary adjunct to its important practical work. After his entry (May, 1881) into the meteorological work of the Signal Service, Professor Hazen took a prominent part in this field. The special works assigned to him (such as the deduction of altitude by railroad levels, the study of the psychrometer, the proper exposure of thermometers, the study of thunderstorms, annual courses of lectures on meteorology), were by no means sufficient to absorb his energies, and we find him branching off into many other subjects, such as barometric hypsometry and the reduction to sea-level, the testing of anemometers, the study of tornadoes and the theories of cyclones, atmospheric electricity, balloon ascensions, the influences of sunspots and the moon, the danger lines of river floods, the sky glows and the eruption of Krakatoa. His enthusiastic advocacy of the importance of the balloon to meteorology was very highly appreciated. His five ascensions (1886, June 24, 25; 1887, June 17 and August 13; 1892, October 27), undoubtedly gave very accurate temperatures and humidities.

* From advance sheets of the *Monthly Weather Review.*

After the death of General Hazen and during the administration of General Greely, the computers of the Study Room became junior professors at a higher salary and were assigned to official duties of a broader aspect. In the course of such duties, Professor Hazen frequently took his turn as forecast official (beginning with October, 1887), and as editor of the *Monthly Weather Review* (beginning with December, 1888), while also acting as assistant in the Records Division. In July, 1891, in accordance with the terms of the transfer to the Department of Agriculture, he was appointed one of the professors of meteorology in the Weather Bureau, where he was at once assigned to regular and congenial duties in the Forecast Division.

Having shown that 'the Hazen thermometer shelter' was much better than the large close double louver formerly used, his form was adopted by the Bureau in 1885 and still remains in use. His experimental work with the sling psychrometer and dew-point apparatus was executed with great care and refinement, but the resulting psychrometer formula differs from those in current use in that it rejects the important term depending on the barometric pressure. Among his larger publications were: *The Reduction of Air Pressure to Sea-level* and *The Climate of Chicago*.

In addition to his official work in the Weather Bureau, Professor Hazen was a frequent contributor to meteorological and other scientific journals. He was one of the supporters of SCIENCE during the years 1882–89 and of *The American Meteorological Journal*, 1884–96. He also, published independently his 'Meteorological Tables,' and 'The Tornado,' and possibly other works. A complete list of his published writings would include several hundred titles.

It must be confessed that a peculiar temperament sometime led him to beliefs and statements in scientific matters unacceptable to his colleagues, but to which he adhered and on which he acted with such pertinacity that to some he occasionally appeared obstinate and headstrong; this was simply a result of the intense earnestness of his own convictions, which so completely absorbed his mind that there was no place for further considerations. However, the amiability of his character always prevented any enduring unpleasant feeling between himself and his associates.

C. A.

SCIENTIFIC BOOKS.

Annual Report of the Bureau of Steam Engineering of the Navy Department; 1899. Washington, Government Printing Office. 1899. Pp. 89. Many illustrations and working drawings.

The annual report of the Chief of the Bureau of Steam Engineering of the Navy Department, made up in advance of the compilation of the annual message of the President and reports of the heads of department for the information of Congress and the people of the United States, always contains interesting matter bearing upon applied science, although mainly devoted to the purely technical side of the work of that bureau. Admiral Melville is equally positive, direct and effective, whether at the Lena Delta seeking lost heroes, or in his office at Washington, and his report illustrates his character as well as his work. Passing over the purely technical accounts of the condition of the mechanisms of the naval war-engine, and of the fleets, the first subject of general interest is that of the recent consolidation of the two great corps, the engineer and the line officers, as effected by the 'personnel bill' of last year. Without explicit assertion of the fact, it may fairly be inferred, we think, that the Chief of Bureau is apprehensive lest the terms of the bill and its purpose may fail of complete accomplishment, the Department lacking that firmness and determination to obey and to make successful the conclusions of Congress regarding this important experiment. It is obviously an experiment and is no less obvious that it may be made to succeed or to fail, accordingly as the officers of the Government, from the President and the Secretary of the Navy down to lieutenant and ensign, combine to insure its success or conspire to insure a failure. It will only be when every watch-officer, whatever his grade, is made an efficient officer, both above and below decks, that the modern naval fighting machine can be made of maximum efficiency under the existing system. Any disinclination of either of the old types of officer to become efficient in either old line of duty, results in serious, perhaps very dangerous, inefficiency, and a liability to failure at critical times. The conversion of the navy from a sailing to a steaming fleet, from an aggregation of sailing craft into a collection of floating machines of wonderfully complicated mechanism, cannot be reversed; but the change may prove most disastrous during the period of transition if every officer in the service does not display sufficient patriotism to insure rapid and safe metamorphosis. It is here that the real risk lies and the overcoming of confirmed habits, of prejudice, and any indolence of the personnel, by reason, sense and patriotism, must be relied upon to insure success.

The structural work of the navy has been greatly promoted by the introduction of a new structural material—nickel-steel; which alloy is now regularly furnished in any quantity and in parts of any size, from five pounds in a rifle-barrel to many tons in the shaft of a transatlantic or Naval steamer. This is an alloy of 'mild' steel, ingot-iron, with a small percentage of nickel, resulting in greatly increasing the limit of elasticity and the ultimate resistance of the metal, without sacrificing its ductility.

Electrically driven machinery has come to be an important and very extensive element in the construction and installation of details of the machinery of every man-of-war. The advantages, where allowable or applicable, are great ease of operation, convenience of energy-transmission, and especially avoidance of heat due to the transmission of steam to steam-driven machinery about the ship, and a considerable gain in economy, in many cases. The disadvantages are stated to be excessive weight, great delicacy, lack of adaptability to the conditions of everyday work at sea, and the occupation of spaces below the protective deck, where space is particularly valuable and difficult to secure for the apparatus of battle. The admiral thinks the advantages of electrical transmissions on shipboard somewhat exaggerated and that, within the machinery compartments, at least, 'steam-drives' are preferable. He refers to the curious fact that, in the navy, it has been the custom, very generally, to entrust the machinery of the electric transmissions to the non-expert departments of the organization. The experts in engineering are apparently called in only when the responsible amateur gets into trouble. As the presumably best-informed man in the navy, on this subject, the Engineer-in-Chief is entitled to most respectful consideration and a full hearing, when discussing these matters of fact and principle in engineering.

The transformation in type of the marine steam-boiler, from the older forms to the 'modern', 'sectional,' 'safety' or water-tube type, appears, in the judgment of the responsible expert authority of the navy, to have been practically accomplished—a change which was compelled as soon as the steam-pressures needed to insure the now common and high thermodynamic efficiencies of naval steam-engines had attained figures beyond the safe standards for 'shell' boilers of the old forms. Now that steam pressure is carried at from 15 to 20 atmospheres, the safer forms employed by Fulton and Barlow in 1798, by John Stevens 1804–5, by Trevithick in 1810, by Gurney and Hancock in 1830–35, and by them made successful in earlier generations and by Babcock and Wilcox and Root later, have come permanently into use. It is somewhat remarkable that they should have been first accepted so generally in the navy, where it has been a tradition that the traditional is best. The change is perhaps in part due to the introduction of a progressive spirit with steam, and certainly largely through the appearance on the scene of the young element now coming up from the great technical and professional school at Annapolis, where it has become imbued with the scientific spirit of the time.

R. H. T.

Bacteriology applied to the Canning and Preserving of Food Products. By EDWARD W. DUCKWALL. Baltimore, *The Trade.* 1899. Pp. xi + 111. 17 colored plates. 7 figures in text. Price, $5.00.

There is great need of a good manual of bacteriology in its applications to the food-preserving industries. The arts of refrigeration and sterilizing have probably done nearly as much as has improved transportation towards abating that unfortunate state of affairs described by Macaulay in which, owing to bad roads, it was no uncommon thing in England, in the seventeenth century, for the fruits of the earth to rot in one place, when only a score of miles away people were suffering from a scarcity of the very food which was spoiling almost within their reach. The author of this 'Bacteriology' is to be commended, therefore, for his recognition of this need and for his evident desire to meet it. The announcement of the work, however, aroused apprehension when it stated that "After some unavoidably long delays, due to the nature of the work which of necessity must be minutely correct and exact * * * the book you have been waiting for * * * is now ready * * * This work, handsomely bound in leather, and printed on heavy paper, contains 24 microscopical views of the living germs found in canned goods in their *natural color*, and just as they appear to the eye under the cover glass. The whole work is written with the express purpose of enlightening and teaching canned-goods packers and preservers of food-products the highest and most scientific method of handling all kinds of foods." It was not encouraging to be thus informed that we were to see 'views of the living germs * * * in their natural color,' and the appearance of the work itself has not been reassuring. A careful examination leads to the conclusion that it has been hastily and even carelessly prepared ; that it is full of errors both of substance and form ; and that the author, while enthusiastic in his appreciation of the importance of bacteriology to his favorite industries, is not himself a trained bacteriologist, but only an amateur filled with zeal rather than knowledge. If, as stated in the announcement, "the whole work is written with the express purpose of enlightening and teaching," it must be frankly said that it is not a success, and that there is danger that it shall darken rather than illuminate understanding among those for whom it was prepared. A few citations will suffice.

In describing certain microscopic observations upon sour tomatoes, the author says on page 2 : "I found quite a number of small round globules, which at that time I was unable to understand. They seemed to be motionless, except a slight quivering which is termed Brownian motion. There were small rods and little fine dots sometimes alone, sometimes in pairs, and looked like ants. There were also small forms barely perceptible and one or two specimens of a very large germ. The view given in the accompanying plate is just as it was taken." The 'view' referred to shows some yeast-like bodies, bacilli and spherules, but the yeast cell walls are colored blue, and the contents of the yeast cells are a mixture of blue dots and red lines. Passing over a multitude of ill-digested and more or less muddy statements, drawn apparently from various authors, but rarely quoted with precision and seldom if ever attributed to the proper source, we may notice one of the more surprising statements in regard to the physiology of bacteria (p. 13) : "Sometimes an acid is generated which will kill them, and that acid may be due to their own action. The condition will become favorable, too, when the organisms have performed their work." Of the butyric acid bacteria the author says (p. 20) : "They are so small in this dried-up form that we can almost conceive of them being able to pass through the juice without becoming wet." And again, on p. 39, " * * * the flavor which is imparted to the beer and wine and the peculiar flavor of cheese and butter we know is due to the products of the butyric ferment, amylobacter." The serious blunder made in this statement appears in another place (p. 7) : "The butyric ferment * * * is so useful in ripening cheese and making butter that this form is cultivated and employed in some of the best creameries."

In regard to Bacillus prodigiosus we find some equally astounding statements (p. 23) : "This is the organism which gives the odor of herring brine or fish to putrefying substances, and is also named 'bleeding bread' because it is a pigment bearing bacillus of red color, and forms spots when growing on bread, potatoes and onion that resemble blood. It is an egg-shaped germ about 1/25000 of an inch in diameter, which is very small * * *. This organism is very common * * *. The drawing here represented was taken from life * * *. [It] is also a germ causing unsoundness in bread and bakers have to guard their dough against this action to prevent souring * * *." The plate which occupies the page opposite this remarkable description is something wonderful to behold. Within a large ten-sided polygon indicated by a thin blue line we have a dozen or more of what appear to be long, stout bacilli or hyphæ, also blue, but showing a reticulum, or chromatin-like substance, of a bright red color. The main background of the field is nearly filled with small, oval, red-colored dots or circles, and besides these there are present n large numbers thin and almost invisible bluei lines which seem to be intended for delicate and very slender bacilli. The legend beneath reads: "Figure 13 Magnified × 1000. One part bouillon, 99 parts water. Rank putrefaction. Bouillon, prodigiosi." The whole effect of this plate must be seen to be appreciated.

Woodhead's excellent book on 'Bacteria and their Products' seems to have been the author's principal source of information, and if he had only quoted correctly, and copied Woodhead's figures with accuracy, there would have been little occasion for the present criticism. One of his worst blunders—to call it by no stronger term—is that in which the author gives as his 'Figure 19. Magnified × 1000. Kleles Loeffler Bacilli, × 1000,' a figure which so far as a careful comparison can determine is a copy of Woodhead's figure not of diphtheria, but of *anthrax* bacilli, and this, too, turned upside down. After discoveries of this sort the intelligent reader may be pardoned for regarding, with a certain cynicism, a rhapsody like the following (p. 31): "What a study it is, then, this science of bacteriology. It opens up a new world to us (*sic*) and we are permitted to gaze upon it and behold the scheme of Nature giving us object lessons day by day in the tearing down and building up process. Life begetting new life and new life flourishes on the dead; seed developing into form, form producing seed, decay of form, and development of seed. This is true of the germ and also of every living thing." As we peruse this strange deliverance we are compelled to agree with the author that form, here at least, readily goes to seed and even to rot.

It would be easy to extend the present review, but the whole work comes dangerously near to a burlesque of bacteriology and extended comment is unnecessary. Only one point more need be made. The author evidently quotes extensively from various writers and investigators without giving them credit. For the most part these statements have long since become the common property of bacteriologists, but toward the end of the book he apparently uses freely the recent and important monographs of Messrs. Prescott and Underwood, of the Massachusetts Institute of Technology, on the history of the canning industry and on bacteriological investigations of canned foods, especially of sour corn, of which a preliminary account was published in SCIENCE, Nov. 26, 1897, and yet never once mentions these authors.

We are tempted to close with the familiar warning that a little knowledge is a dangerous thing, and a reminder to those into whose hands the book may fall that blind leaders of the blind are apt to be untrustworthy. The author himself, in discussing the vacuum which exists in most well prepared and hermetically sealed food-cans, has, however, given utterance to a similar warning, in quite original metaphor: "We thus see that packers who are pinning their faith to a vacuum are depending upon a broken reed." Those who pin their faith to the author's kind of bacteriology will, we fear, discover to their cost that they are leaning not even upon a broken reed, but only upon a vacuum.

BOOKS RECEIVED.

Lehrbuch der Botanik für Hochschulen. EDUARD SRASBURGER, FRITZ NOLL, HEINRICH SCHENCK, A. F. W. SCHIMPER. Jena, Fischer, 1900. Fourth revised edition. Pp. viii + 588. 7 Mark, 50 Pf.

The Nature and Work of Plants. DANIEL TREMBLY MACDOUGAL. New York and London, The Macmillan Company. 1900. Pp. xvii + 218. 80 cts.

A Manual of Zoology. C. JEFFREY PARKER and WILLIAM A. HASWELL. New York and London, The Macmillan Company. 1900. Pp. xxv + 563. $1.60.

Optical Activity and Chemical Composition. H. LANDOLT, translated by JOHN McCRAE. London, Whittaker & Co.; New York, The Macmillan Company. 1899. Pp. ix + 158.

The Refraction of the Eye. A. EDWARD DAVIS. New York and London, The Macmillan Company. 1900. Pp. xii + 431. $3.00

SCIENTIFIC JOURNALS AND ARTICLES.

The Osprey for January begins with a paper by Paul Bartsch on 'Birds of the Road,' which is followed by an illustrated article on 'Esthetic Birds; The Bower Birds of Australia and New Guinea,' by Theodore Gill. Under the title, 'The Birds of the Hawaiian Islands,' Leonhard Stejneger reviews Scott Wilson and Evans' monograph of the Hawaiian birds and discusses some of the many interesting points connected with the avifauna of the islands. Charles E. Beecher contributes a sketch of 'Othniel Charles Marsh as an Ornithologist,' and gives a list of the fossil species described by him. The editorials contain some interesting statements as do also the notes.

Bird Lore for February opens with a brief, but appreciative biographical sketch of the late Dr. Coues, accompanied by an excellent portrait. Frederic A. Lucas contributes an illustrated article, 'Concerning Birds' Tongues,' and Frank M. Chapman has a 'Note on the Economic Value of Gulls,' which includes a very beautiful picture of a group of kittiwakes. A list is given of '*Bird Lore's* Advisory Council,' whose members have consented to assist students by responding to their requests for information. Lynds Jones discourses 'On Methods in Teaching Ornithology at Oberlin College' and W. H. C. Pynchon has a paper on 'Every-Day Study of Birds for Busy People.' Morgan St. John (aged 12) has an article on 'February Birds,' which shows that good observations may be made by a young observer. There are numerous notes and book reviews, and in the editorial department the question of bird protection is discussed at length.

The Plant World commences its third year with the January number and announces that a series of articles by Mr. Pollard on the families of flowering plants will appear as supplements to each number. C. F. Saunders describes the 'New Jersey Pine Barrens in July,' Wm. T. Davis has some 'Observations on a Woodland Fire,' and C. A. Crandall under the caption 'The Fall Green Orchis (*Habenaria hyperborea*) visited by Mosquitoes' tells how these insects assist in the pollination of this plant. V. K. Chestnut discusses a 'Fatal Case of Amanita Poisoning' and Mrs. Caroline A. Creevy continues the series of articles on 'Plant Juices and their Commercial Values.'

McClure's Magazine for October contained a short story entitled 'The Killing of the Mammoth,' which was taken by many readers, not as fiction, but as a contribution to natural history. Numerous requests for information have been received by the Smithsonian Institution and the editors of the magazine. To explain matters, the editors have inserted in the issue for February an interesting and excellently illustrated article by Mr. F. A. Lucas of the U. S. National Museum, entitled 'The Truth about the Mammoth.'

SOCIETIES AND ACADEMIES.

THE PHILOSOPHICAL SOCIETY OF WASHINGTON.

THE 511th meeting of the Society was held at 8 p. m., on January 20th at the Cosmos Club, Surgeon General Sternberg, presiding.

Under the head of Informal Communications Professor T. J. J. See of the Naval Observatory, presented the results of his researches on the orbits of the Double-Stars τ Cygni and 95 Ceti. The substance of the paper was as follows: No good orbit of either star has been determined by previous investigators. The period of τ Cygni was found to be 57 years, and the eccentricity 0.37. The companion, which is always very difficult, has passed through periastion, and is slowly becoming easier to observe. 95 Ceti is the most difficult of known Double-Stars, and only a few measures have been made by previous observers. So many unsuccessful attempts had been made by Burnham and others during the last twenty years to separate the small star, that some astronomers had reached the conclusion that the system is in very rapid motion, with a period of perhaps less than ten years. But the recent measure secured by Professor See with the great Equatorial of the Naval Observatory, combined with others taken by him with the Lowell telescope in Arizona in 1897, show that the System in fact revolves slowly with a period of about 150 years. The present position-angle is 157°, and the distance 0.33. As the components are of the 6th and 11th magnitudes, the difficulty of the investigation is apparent. This star has not before been seen at Washington, and Professor See's success in observing it led him to think the seeing here is occasionally very good indeed. As the companion of 95 Ceti will remain at a constant distance for about 20 years it forms a test object for telescopes which will prove a useful criterion for observers.

The first regular paper was by Dr. Hyvernat, Professor at the Catholic University of America, who made a tour last summer in Syria for the purpose of ascertaining the cause of the perennial fountains so numerous in the Middle Region, or Wusut, of the Lebanon System. Special attention was given to the Province of Kesrawan which he explored from west to east, following the Nahr-el-Kelb and its chief tributary, the Nahr-el-Zalib, until he arrived at the Sannin Group. He discovered that the juncture of the main with the side-ridge, which runs in a northwesterly direction between the basin of the Nahr-el-Kelb and that of the Nahr-Ibrahine, forms a table-land sloping towards the north-west and studded with gigantic, rocky knobs. Between these knobs are numerous holes in the shape of craters, or funnels, filled with snow. Finding these holes entirely without outlet on the sides and without an exception, free from water, Dr. Hyvernat came to the conclusion that as the snow melts, the water filters immediately through fissures in the underlying rock and appears again at the foot of the High-Mountain, or Jurd, in the form of the aforementioned fountains. This to him seemed a better solution of the question of the origin of the fountains, than the theory of the condensed vapors, put forth by many geographers. Completing his own observations from those of E. H. Palmer and R. F. Burton, the lecturer remarked that Mount-Lebanon offered very likely the most extensive system of perennial fountains fed by 'snow-swallowing' holes. Dr. Hyvernat showed quite a number of specimens of geology, particularly from the lower cretaceous and the Nubian sandstone.

The second paper was by Mr. Mitchell Carroll on 'Recent Excavations in the Roman Forum.' Mr. Carroll said that the excavations in the Roman Forum, conducted during the past year under the direction of Signor Guido Bacelli, Minister of Public Instruction, and with Signor Giacomo Boni as superintendent, have shown gratifying results, especially in three directions: First, in the removal of mediæval and modern accumulations from certain ancient structures, and in the collecting and classification of the architectural fragments scattered about in the Forum; second, in the reconstruction of the temple of Vesta and *Ædicula* adjacent to it, and of a number of the honorary columns, whose pedestals front the Basilica Julia; and third, in the excavation of the area of the Comitium bordering on the Forum which has led to the discovery of what purports to be relics of the period of the Kings. These are: the 'Niger Lapis,' popularity designated the 'Tomb of King Romulus'; archaic votive offerings, (such as a terra-cotta tablet, bronze figurines, etc.); and above all in importance, a stelé, bearing an archaic inscription, supposed to date from about the middle of the seventh century, B. C. The lecture was illustrated by lantern slides showing the progress of the work.

E. D. Preston,
Secretary.

GEOLOGICAL SOCIETY OF WASHINGTON.

The 96th regular meeting was held at the Cosmos Club, January 24, 1900.

The following papers were presented on the regular program.

(1) Mr. C. W. Hayes: 'Solution Sinks in a Quartzite Formation.'

Two circular depressions, 150 feet in depth, occur on the southern flanks of Coldwater Mountain in Alabama. These depressions have all the characteristics of solution sinks. The rocks in which they occur are lower Cambrian quartzites and sandstones, the upper beds of the Weisner formation, which has a thickness of several thousand feet. The explanation offered for these sinks is that the beds in which they occur have been faulted over beds of limestone, and the material which originally occupied the depressions has fallen into underground channels through which it was carried off by flowing water.

(2) Mr. J. E. Spurr: 'Structure of the Basin Ranges.'

This paper describes the structure of many hitherto unstudied ranges in southern Nevada. The general structure is a series of open regular folds, with general north and south axes, accompanied by occasional parallel and transverse faults. Folding and faulting have gone on continuously since the region was upheaved at the close of the Jurassic. The present mountains owe their forms chiefly to erosion, which has been in progress, synchronously with the folding and faulting, since Jurassic time. The more common types are anticlinal ridges and synclinal valleys. The mountains are the compound result of erosion on rocks upheaved by these compound movements.

F. L. RANSOME,
DAVID WHITE,
Secretaries.

NEW YORK ACADEMY OF SCIENCES.

SECTION OF GEOLOGY AND MINERALOGY.

AT the meeting on January 15, 1900, with Mr. G. F. Kunz in the chair, there were twenty persons present.

A report was presented by Professor J. J. Stevenson in behalf of the committee appointed November 20, 1899, in reference to the death of Sir William Dawson, of Montreal. On motion by Professor D. S. Martin, the report was adopted and recommended to the Council for printing.

The Chairman called attention to the coming meeting this year, in Paris, of the Eighth Session of the International Geological Congress, described the proposed excursions, and suggested the earnest coöperation of the Section by delegates, contribution of papers and financial aid. On motion by Professor J. F. Kemp, the matter of the representation of the Academy at the International Congress was referred to the Council for action.

A paper was read by Professor F. B. Peck 'On Serpentines and Talcs in the Vicinity of Easton, Pennsylvania,' with abundant illustrations by specimens of rocks, diagrams and lantern views.

In the subsequent discussion Professor Kemp stated that, in the talc deposits on the west side of the Adirondacks, described by Professor Smyth, the derivation of the talc had been attributed to the magnesium limestone or intrusion of a magnesium silicate rock.

Professor Peck replied that he considered the tremolite rock to be due to the alteration of a siliceous dolomite; the talc, possibly to the interchange of silica from the pre-Cambrian gneisses and magnesia from the adjacent dolomite limestone.

The serpentine and 'viridolite' had indeed been subjected to much shearing and fracture, but had been solidly re-cemented, so that they they could be quarried out in large blocks, free from cracks—sometimes of twenty tons weight, in the case of the 'viridolite.'

Professor J. J. Stevenson then discussed 'C. E. Bertrand's Theory respecting the Origin of Certain Coals.'

Mr. F. E. Lloyd remarked that the cells of algæ, to whose accumulation Bertrand and Rénaud mainly attributed the formation of these coals, are exceedingly delicate and often mucilaginous. Those of *sphagnum* are much thicker, solid and woody, and yet a large quantity of this is required to produce much deposit of carbonaceous matter in swamps.

The Chairman inquired whether freezing or the introduction of silty waters might cause the precipitation of ulmic acid referred to by these authors.

Professor Stevenson stated that ulmic acid so precipitated would tend to carry down suspended matters and to clear the waters.

A paper by Mr. H. Ries was then read, 'Note on the Occurrence of Allanite in the Yosemite Valley, California.'

While in the Yosemite Valley in September, 1899, my attention was attracted by a black, coaly-looking mineral in the pegmatite veins on the northwestern side of the Valley. On closer inspection the mineral proved to be allanite, and as it has not yet been recorded from this region, it seems of interest to note the fact.

The rock forming the walls of the Yosemite is a grano-diorite according to Turner (17th Ann. Rep. U. S. G. S., pt. I., p. 710). Traversing this in many directions are veins of pegmatite, which are sometimes straight and unbroken, at others curved, branched, or even broken into. These pegmatite veins are very prominent on the face of El Capitain, and also in the rock forming Eagle Peak. It was in the talus at the foot of the latter that the allanite was found, and while the mineral was at times abundant in the pegmatite blocks, still none of it was noticed in the grano-diorite. In only one instance was a distinctly bounded individual found, and on this a combination of orthopinacoid and base were recognizable. The other specimens were irregularly bounded grains that varied from a sixteenth to a quarter of an inch in diameter.

In addition to the quartz, muscovite and orthoclase present in the pegmatite, there were a number of radiating masses of epidote, which were evidently of primary origin; but in two instances the epidote occurred as a coating on hornblende and then seemed to be secondary. None was found in association with the allanite.

In conclusion, it may be said that it is interesting to find that allanite is evidently not the rare mineral that it was formerly considered to be, and that a careful watch is beginning to show its presence at many localities in the United States.

Alexis A. Julien,
Secretary of Section.

ONONDAGA ACADEMY OF SCIENCE.

At the January meeting the following officers were elected: *President*, John Van Duyn; *Vice-President*, J. D. Wilson; *Recording Secretary*, E. N. Pattee; *Corresponding Secretary*, H. W. Britcher; *Treasurer*, Miss L. W. Roberts; *Librarian*, Mrs. L. L. Goodrich; *Councilors*, G. A. Dakin, H. A. Peck and W. M. Beauchamp.

The annual report of the Geological Section showed that several investigations of local problems are being carried on and that some have been already completed during the year.

The report of the Zoological Section noted the occurrence within the county during the past year of the Bohemian wax wing, *Ampelis garrulus*, the jumping mouse, *Zapus hudsonius* and the hairy-tailed mole, *Parascalops breweri.* Additional localities were indicated for planaria, bryozoa and hydra. During the year fifty moths were taken, thus bringing the number of Lepidoptera of the county to over 600.

The report of the Botanical Section added the following plank to the county list: *Hyssopus officinalis*, *Chenopodium anthelminticum* and *Polygonum lapathifolium* with new stations for *Crepis virens*, *Glaucium glaucium* and *Scolopendrium.*

At the January meeting of the Geological Section, Professor E. N. Pattee reported on the progress of the investigations of the iron compounds of the county. The chief sources of these compounds are the red shales of the Salina formation, yielding small scales and flakes of hæmatite, the Corniferous, yielding crystals of pyrite and the Oriskany sandstone, yielding from one to five per cent. of iron, the color of the stone being, however, no index to the amount of iron, existing as a cement, which the rock contains.

H. W. Britcher,
Corresponding Secretary.

THE TEXAS ACADEMY OF SCIENCE.

During the last quarter of 1899 regular meetings of the Texas Academy of Science were held in the chemical lecture room of the State University on the second Friday evening of each month.

On October 13th, after a proper tribute to the worth and work of the late Dr. W. W. Norman, Professor of Animal Biology in the University and one of the most active members of the Academy, in which Messrs. Bray, Harper, Garrison, Sutton and others participated, Dr. Frederic W. Simonds, the incoming president, read his inaugural address, 'From the Standpoint of a Man of Science,' in which he made a vigorous protest against sham in all things, but especially in science, and an earnest effort to explain many of the popular misunderstandings of science and misconceptions concerning men of science and their work.

At the October meeting, Professor W. S.

Sutton, of the School of Pedagogy, read a timely and exceedingly interesting paper upon the 'Bachelor of Arts Degree,' in which he showed the origin of this ancient honor and its evolution until at the present time it stands for culture, and, in several prominent American institutions, has even become the sole mark of academic training.

The program for the December meeting was of two parts. The first, representing original investigation, consisted of two papers by Mr. E. T. Dumble, formerly State Geologist, entitled 'Cretaceous of Obispo Cañon, Sonora,' and 'Occurrence of Oyster Shells in Volcanic Deposits in Sonora, Mexico.'

Part second was of the nature of a symposium, in which the advancement of science during the past year occupied a conspicuous place. Dr. William L. Bray, discussed the 'Modern Trend of Botanical Studies,' showing clearly and forcibly the enormous strides made within the last few years; he pointed out the differentiation of the science of botany—how it had outgrown the grasp of any one man—and spoke briefly of its economic relations to many important industries.

Dr. Henry Winston Harper discussed the 'Recent Advances of Chemistry.' The solidification of hydrogen was, in his opinion, the most important chemical contribution to science during the past year. From a thermo-dynamic standpoint it is one of the greatest accomplishments of the nineteenth century, as it requires a temperature within 15° C. of the absolute zero. The study of the properties of matter at such extremely low temperatures is a virgin field for original investigation and phenomena of a most startling character may be looked for here. Some of the results of the latest research along this line were brought before the Academy. The advances of chemistry along many other lines were also discussed, especial stress being given to the recent utilization of the Indian corn plant, or maize, not only of the grain, but of the entire plant—pith, stalk and leaves. Professor Harper closed his discussion by reference to some recent developments of chemical theory, devoting particular attention to 'Werner's Theory of Coördinated Types.'

At a meeting of the Council, following this public session, Drs. Hilgartner, Bray and Bailey, were elected a Committee on Publication.

University of Texas.

DISCUSSION AND CORRESPONDENCE.

FALSE BIBLIOGRAPHIC INDICATIONS.

To the Editor of Science: For some years past a few scientific Hamlets have been trying to set the time right in the matter of 'authors reprints,' 'Separat-abdrücke', or 'tirages à-part.' The most essential of their demands is that such separate copies should be furnished with correct bibliographic indications, and should retain the original page-numbers. They recognize with gratitude that the last ten years have witnessed a vast improvement in this respect. But a new terror has arisen, and appears so frequently and in so many quarters that it seems time to raise a vigorous protest.

It is not uncommon to be favored by an author with a copy of his latest work giving the desired bibliographic indications—name of periodical, volume, page, and plate numbers, and date of publication—and apparently with the type undisturbed. But should some chance lead one to the original, one finds that one or more, perhaps all, of these indications are incorrect; or else that the type has been shifted, so that matter appears on a page other than that which it originally occupied. Direct misstatements of this specious nature are worse than no statement at all.

It is not gracious to look a gift horse in the mouth, but some instances will make the point clearer and may serve as a warning. Be it understood that this is no question of mere incompleteness of information, simple repaging, or even incorrect dating, for examples of these offences are familiar to every serious worker and are remedied by him in due course. But take such a case as this: "Studier öfver den baltiske Yngre kritans bildningshistoria. Af Anders Hennig. Aftryck ur Geol. Fören i Stockholm Förhandl. Bd. 21, Häft 1., 1899." The pagination runs from 19–82, and appears to be, as indeed it is, the original pagination. Then comes 'Häft 2' and the paper is said to be continued from the preceding 'Häft.' The pagination also continues, 83–138. There is nothing to show that this is not the original pagination, and only the reader who chances to look up the original will find that the numbers should be 133–188 (with an addendum, not in the author's copy, on p. 218). Familiarity with the publications of the Stockholm Geological Society might arouse suspicion of the above. Let us turn to a case which seems a veritable Caesar's wife, extracted, as it is, 'from the Proceedings of the International Congress of Zoology, Cambridge, 1898,' edited by a very important person and printed by the University Press. It is 'On the Origin of Echinoderms, by Professor E. W. MacBride.' It bears all the characteristic signs of having been lifted without a tittle of alteration from the *Proceedings*, and the page numbers are 141–147. But in the *Proceedings* this paper appears on pp. 142–148.

Our next awful example hails from a Society which has done much to facilitate the work of zoologists: "Accidents will happen, etc." The paper is "Troisième note preliminaire du yacht *Princesse-Alice* * * * par E. Hérouard. Extrait du *Bulletin de la Société zoologique de France*, tome XXIV. * * * page 170." The pages of the extract continue regularly to page 176. Imagine the disgust of a Zoological Recorder, after entering all the new species-names on his slips, when he discovers by the merest chance that the original pages are 170–175 (not 176 at all) and that the type on every single page has been shifted. The converse of this Procrustean trick has been played upon "Notes biologiques sur quelques espèces d'Alphéidés observés a Djibouti, par H. Coutière. Extrait du *Bulletin du Muséum d'histoire naturelle*, 1897, no. 8, p. 367." The original pages, up to 370, are carefully given in [ ], and who would guess that there was ever a page 371, or that half of the text was on its wrong page? It is almost fortunate that the omission of the volume number and of the date of publication forces one to look at the *Bulletin* itself, and so discover the error.

After this one does not wonder at the following enigma recently received from a British Colony: "On some Cambro Silurian and Silurian Fossils from Lake Temiscaming, Lake Nipissing and Mattawa, by Henry M. Ami. * * * Extra. Ann. Rep. Geol. Surv. of Canada, Vol. X, Part I, Appendix II, pp. 282–301, Ottawa; Sept. 1899." Thus runs the wrapper. The title in the text adds "outliers" to the title; but a wrapper-title is not supposed to be correct. (*Why* not?). The pages of the text are 2891–3021. These figures are not merely irreconcilable with those on the wrapper, but suggest that "Part I" does not mean "Part One" at all, since the I is probably intended as a letter of the alphabet not as a Roman numeral. But this riddle is not yet solved, since the *Report*, here said to have been published four months ago, has not yet crossed the Atlantic.

These instances have not been selected for their intrinsic importance, but just as samples, all received within a few days of one another by a single individual. Each in itself seems trivial, but even a professional in touch with the best libraries in the world will be lucky if he can correct these five references in less than an hour. If he innocently accepts them he must not be surprised if he is abused some day as a careless worker, and his purely scientific observations mistrusted. If he incorporates them in a professed bibliography, the accuracy of his work will ever after be suspected and its value thereby seriously impaired.

Now the *fons et origo malorum* is not the author, who has very little to say in the matter, but the printer with his curious conventions of space and form, and his excusable ignorance of the needs of the working naturalist. The remedy lies, if anywhere, in the hands of the editor: he, who has the power, should also accept the responsibility. If the editors of our scientific publications would but realize the perpetual inconvenience that is caused by a little want of thought, and would but give clear and definite instructions to their printers to place the required bibliographic indications at the head of each reprint, to retain original pagination, and never to shift the type without duly stating the fact—then the amount of time saved by the numerous workers who have to rely upon authors' copies would be far greater than most people have any idea of.

F. A. Bather.

Natural History Museum,
London, 20 Jan., 1900.

FOSSIL-HUNTING IN WYOMING.

EDITOR OF SCIENCE: An article on 'Fossil-hunting in Wyoming,' published in the January issue of *The Cosmopolitan*, contains some inaccuracies which ought to be corrected. The present writer feels called upon to make these corrections. As many of the illustrations used in the *Cosmopolitan* article were from photographs of the Field Columbian Museum quarries, the erroneous impression has gone out in certain quarters that members of this institution were responsible for some of the misstatements, especially one which has been interpreted as a reflection upon a man to whom the science of paleontology owes much. I wish, therefore, to give a brief history of the discovery and collection of Dinosaurs in America, which I have sought to make as accurate as possible. The data regarding their discovery and early collection have been furnished me by Dr. Williston, whose association with Professor Marsh during his early work upon the Dinosaurs places him in position to speak authoritatively.

The first Jurassic fossil discovered in America was described in 1870 by Leidy under the name *Antrodemus* (*Labrasaurus*, Marsh, *fide* Lucas). Professor Arthur Lakes of Golden, Colorado, was, however, the first to recognize and appreciate the value of the deposits. In March, 1877, he located the horizon near Morrison, Colorado, and immediately sent specimens to Professor Marsh. Almost contemporaneously but a little later, fossils were discovered at Cañon City, Colorado, by O. Lucas, a teacher, and in Wyoming by W. H. Reed, a section foreman on the Union Pacific railroad. Reed, however, did not make known his discoveries until the following autumn and so forfeited any claim to priority.

In December of the same year Dr. Williston, who had been collecting for Marsh at Cañon City and later at Morrison, was sent to investigate the discovery reported by Reed at Como, Wyoming. Under his directions and assisted by Reed, quarry 1. of the Como series was at once opened and the work continued until late in the winter. During the succeeding years collecting was actively carried on in the Como region and as many as thirteen quarries in all were opened by the various men who had charge of the work. Collecting was carried on exclusively by Marsh for two or three years, at the end of which time Cope sent men into the immediate vicinity. After the Como quarries were abandoned, no collecting was done in the Jurassic beds for a number of years and the impression went out that the locality was exhausted. Interest in the beds was, however, revived by Professor W. C. Knight of the University of Wyoming, and W. H. Reed, who as early as the summer of '94 located and opened a new quarry at Mexican Mines, Wyoming. In the following summer Dr. Williston with a party from Kansas University was invited to share with them their new prospect. In '96 collecting was continued by the University of Wyoming in the Jurassic beds south of Laramie. In the spring of '97 the American Museum of New York sent men into the old Como locality to reopen Marsh's mammal quarry; but finding more promising material in the Dinosaur beds, their attention was turned to them. About the same time Knight's men opened quarries in the Freeze-out Hills. During the following year collecting was actively carried on by these two parties in their respective localities, and valuable quarries opened by both.

In '99 unusual attention was attracted to the Dinosaur beds of Wyoming by various press reports more sensational than accurate. In addition to the two institutions which had been carrying on active work, parties were sent out by the University of Kansas and by the Carnegie and Field Columbian museums. The Union Pacific railway also organized an excursion to the fossil fields, which brought not only paleontologists and geologists, but men interested in almost every branch of natural science to look at this new Eldorado. Among the new quarries opened during the year, those of the Carnegie Museum and Kansas University proved especially productive.

The valuable deposit worked out by the Field Columbian Museum party had not previously been passed over by 'a Kansas University professor,' as stated by the author of the *Cosmopolitan* article. On the contrary the quarry had been located and worked for some time by the Kansas University men. After they had taken out a large quantity of unusually good material and returned home, the Field Museum party made a new stripping beside the old and obtained from it large additions to its summer's collection. Photographs of the fossils exposed in the various stages of the work of this party formed the subjects of many of the illustrations used in the *Cosmopolitan* article.

ELMER S. RIGGS.

FIELD COLUMBIAN MUSEUM.
January, 23, 1900.

CURRENT NOTES ON PHYSIOGRAPHY.

PHYSIOGRAPHY OF JAMAICA.

IN connection with his studies of coral reefs, Mr. Alexander Agassiz has had surveys made of several West Indian islands by R. T. Hill, whose latest report is on the 'Geology and Physical Geography of Jamaica' (Bull. Museum Comp. Zool., Harvard College, xxxiv, 1899, 256 p., xli pl., including a topographical and a geological map). The island contains an interior mountainous area (the Blue mountains, 7360 feet), of greatly deformed rocks and of well subdued and elaborately carved form, occupying about one-sixth of the total area, chiefly in the east. A limestone plateau, whose gently arched strata were deposited unconformably upon the denuded older rocks during a period of submergence, rims around the eastern mountains and covers the central and western parts of the island to heights of 3000 feet; it is terminated toward the coast by strong bluffs, often terraced, 1200 feet high on the north. Below the bluffs, low plains descend gently to the sea. Solution has exerted great control over the drainage of the plateau, as may be seen in the interesting series of depressions, from incipient hollows of small size, to deep 'cock-pits' or sink-holes, and great basins, walled in by strong cliffs. Some of the basins still have underground drainage; others discharge their waters through canyons that have been formed by the retrogressive erosion of exterior rivers; while still others have lost their outer wall by the greater advance of erosion, subaërial or marine, and now form amphitheaters open to the coast. Inliers of older rocks sometimes rise in mountain form from the floor of the larger basin, as in Clarendon valley in the center of the island. The strata of the coastal plains lie on denuded benches of limestone or older rocks; their surface is diversified by coral reefs and transverse valleys, the first deposited, the second eroded during the time of elevation. The largest plain is that of Liguanea, upon which Kingston is situated.

The geological structure and history of the island, and its relation to the surrounding regions are fully discussed.

NICARAGUA CANAL ROUTE.

No article recently published gives better illustration of the practical value of the explanatory or genetic method in geographical description than that by Hayes on the 'Physiography of the Nicaragua Canal route' (*Nat. Geogr. Mag.*, x, 1899, 233–246; see also SCIENCE, x, 1899, 97–104). One feels on reading it that the author has critically observed the salient facts and that his account of them fully expresses the results of his observations. The region described may be divided into three parts: The upland traversed by the San Juan river from Lake Nicaragua eastward to the Carribbean, the basin of the lake, and the upland or continental divide that separates the lake from the Pacific. The eastern upland is part of an uplifted and dissected peneplain, 100–200 feet above sea level, and bordered by hills and mountains on the north and south. Its revived streams still run nearly at the upland level in their upper courses; then they descend rapidly in young valleys that they are still deepening to aggraded alluvial floors, which suggest a recent depression after the time of first valley cutting. The lake now stands where a bay once opened northwest to the Pacific; the eastern upland was then the continental divide. The bay seems to have been formed by warping or faulting a western portion of the peneplain above referred to. Numerous volcanic cones grew on the bay floor and converted its head into the lake, whose level rose until an eastern overflow formed the San Juan river, now cutting a trench across the eastern upland. The southwestern barrier of the lake seems to be another part of the peneplain, warped so as to give a steep descent to the Pacific and a gentler descent to the lake. On account of the unequal slopes thus determined, several Nicaraguan streams have lost their headwaters to the Rio Grande, which enters the Pacific at Brito; and the point where one of the now beheaded Nicaraguan rivers rises on its old valley floor is the lowest pass on the present continental divide, and hence is selected for the path of the canal from the lake to the ocean. A fuller discussion of the region is given by the same author in *Bulletin of the Geological Society of America* (x, 1899, 285–348).

THE PLAINS OF RUSSIA.

A NOTE in SCIENCE, May 2, 1898, was in error in describing the plains of central Russia as dipping under the drift sheet on the northwest. The plain is continuous across the older rocks and the drift sheet of the first glacial invasion, and both areas are to-day dissected similarly by valleys. Philippson returns to this subject (*Pet. Mitt.*, xlv, 1899, 269–271) to emphasize his conclusion that the paleozoic and mesozoic area of the plain is a surface of denudation, now broadly uplifted and somewhat dissected; the denudation being completed contemporaneously with the formation of the drift plain. The rivers may have followed shallow depressions in the surface of the great plain, but the valleys of to-day are undoubtedly the work of erosion after uplift, and hence all of quaternary date. Even the broad and unsymmetrical valley of the Volga is held to be of later origin than the first glacial epoch. Small rivers have cut valleys 100 meters deep, either entirely in the older rocks, or in the drift area, or passing back and forth from one to the other. Most of the valleys are of a considerable width already, with well graded floors; but where the Dneiper crosses the granite swell of southwestern Russia there are rapids in its course. Philippson urges that the solution of morphological problems of this kind should not be postponed until the completion of detailed geological surveys, but that they should be studied during the prosecution of the surveys; he also wishes fuller information from the Russian geologists concerning the date of folding in the Urals and of their later upheavals after extensive denudation.

THE AMALFI LANDSLIP.

THE Boston *Transcript* of January 13th gives a translation from an Italian newspaper, *La Tribuna*, describing the landslip at Amalfi on December 23d, last. For several days preceding the disaster a trembling motion had been noticed in the mountain over the town and many peasants had left their houses. Early on the morning of the 23d, a noise like that of splitting wood was heard in Hotel Santa Caterina on the mountain slope, and a crack was found in one of the walls. A man from a quarry brought news that a small fissure had opened in the mountain side. Soon afterwards stones began to roll down the steep slope at more and more frequent intervals, and then a mass of rock estimated at 30,000 cubic meters broke away from the mountain and fell with terrible noise, crushing everything in its way and raising a dense cloud of dust. Some peasants working on the upper slope saw a long fissure open 'beneath their feet' and had only time to leap aside before the ground on which they had been standing broke away and fell. Others working at a lower level were killed. The sliding mass swept away a peasant settlement on the upper slope, buried the Hotel Caterina, crushed one end of the old monastery known now as the Hotel Cappuccini, a favorite resort of travellers, and then ran into the sea, destroying two boats, capsizing two others, and obstructing the shore waters. The highway near the shore was covered and all travel on it was suspended for fear of later disasters. Along the track of ruin for some distance up the mountain side, houses are demolished, trees uprooted, and gardens overwhelmed. A number of lives were lost, and the damage is estimated at over 1,000,000 lire.

W. M. DAVIS.

CURRENT NOTES ON METEOROLOGY.

A NOTEWORTHY BALLOON VOYAGE.

AN interesting point in connection with a recent balloon trip is noted in the *Zeitschrift für Luftschiffahrt* for December. The trip in question was made by MM. de Saint-Victor and Mallet, starting from Paris on September 30th last, at 6:15 p. m., and landing near Vestewick, in Sweden, on the evening of the following day. The duration of the trip was 23¼ hours, and the distance passed over was 1330 kilometers, or about 825 miles. The point referred to concerns the effect of a water surface upon the temperature of the air at the altitude of the balloon (about 500 meters). At about 9 a. m. on October 1st the balloon began to drift over a part of the Baltic Sea, and the aëronauts at once noticed a fall in temperature and an increased humidity in the air through which they were moving. In consequence of these changed conditions, the balloon began to descend, and it was necessary to throw out ballast in order to maintain it at a proper altitude.

THE BAGUIOS OF THE PHILIPPINE ISLANDS.

In the *Monthly Weather Review* for October, Abbe notes that in speaking of tropical cyclones, the word *cyclone* should uniformly be employed for all revolving storms, or else that names should be used which have a widespread local usage. Thus the term *hurricane*, which has its root in the Carib word *ourgan*, should, at least in English works, be restricted to the violent tropical cyclones of the North Atlantic Ocean. *Typhoon* has been the recognized designation of the revolving storms of the China Sea for many years. And now the term *baguio*, which is commonly used by the Tagalogs and Viscayans seems likely to come into use. *Baguio* is the name universally applied in the Philippine Archipelago to the storms that, after they pass westward over the Archipelago, become *typhoons* on the coast of China.

THE DROUGHT IN INDIA.

It has for some time been the custom of the Indian Meteorological Department to issue long-range forecasts of the monsoon and cold weather rains in India. From *Nature* for January 11th we learn that this year the forecast of the cold weather (December–February) rains in northern and central India anticipated a rainfall slightly above the normal. The prediction has unfortunately not been verified, as an area comprising nearly two-thirds of India is now suffering from the most severe drought of the century, and there does not seem, at present, to be any immediate chance of a change for the better.

METEOROLOGICAL CHART OF THE GREAT LAKES.

There has been issued by the Weather Bureau a publication entitled *Meteorological Chart of the Great Lakes: Summary for the Season of 1899*, by A. J. Henry and N. B. Conger. This quarto pamphlet summarizes the information contained in the monthly meteorological charts of the Great Lakes, issued throughout the navigation season. The discussion concerns the storms of the year; precipitation and the possibility of evaporation in the Lake region; fog; ice during the winter of 1898–99, and the wrecks and casualities which occurred during the year. A dozen charts illustrate the text.

R. DeC. Ward.

WAGNER FREE INSTITUTE OF SCIENCE.

The lectures for the spring term at the Wagner Free Institute of Science will commence on Monday, February 12, 1900. The following is the schedule:

Mondays, Dr. Henry Leffman, 'Chemistry.'

Tuesdays, Professor W. B. Scott, 'Dynamical Geology.'

Wednesdays, Professor R. E. Thompson, 'American History, 1783–1865.'

Thursdays, Professor G. F. Stradling, 'Heat.'

Fridays, Professor S. T. Wagner, 'Metallic Materials of Engineering Construction.'

Fridays, Professor T. H. Montgomery, 'Invertebrate Animals.'

Saturdays, Dr. Emily G. Hunt, 'Some Aspects of Botany.'

At the annual meeting at the Institute Mr. G. H. Cliff, formerly president of the Girls' Normal School, was elected a trustee to succeed the late Richard B. Westbrook, Esq.

From the report of the Actuary it was learned that 13,828 persons had attended the Fall course of lectures, that 28,378 persons had used the Reference Library and that the Branch of the Free Library had circulated 269,618 volumes for home use; 1327 books and 2226 pamphlets and magazines were added to the Wagner Institute Reference Library during the year. The report dwelt at some length upon the splendid collection of government documents owned by the Institute, probably the best in the City of Philadelphia, which was now classified and was being thoroughly catalogued. The thanks of the Board were extended to the officers of the Spring Garden Institute for an important addition to this collection.

The Board has given permission to the Philadelphia Natural History Society to hold its meeting in the Institute. This Society is in a most flourishing condition and there is an average attendance at the meetings of from 35 to 40 persons.

The number of accessions to the Museum during the year was 386, making a total of 14,880 exhibits, not including the insects of which there are about 5000 species. The collection of Florida Pliocene Fossils is one of the best and most complete in the country. Among the most important contributions are 100 species of fossils collected by Dr. H. G. Griffith on the Caloosahatchie River, Florida; 50 species of minerals presented by Mr. Joseph Wilcox, a number of zoological crustacea and mollusks collected by the Zoological Expedition to Florida in June, 27 local species from the Academy of Natural Science Exchange, 22 species of birds and nests from J. Harris Reed, and a collection of coal plants from the Rock Hill Coal and Iron Company. The local collection of insects is now the most complete in the City.

SCIENTIFIC NOTES AND NEWS.

MAJOR J. W. POWELL, director of the bureau of American ethnology, and Professor W. H. Holmes, head curator of anthropology in the United States National Museum, are in Cuba engaged in carrying out a plan for archæologic researches which are expected to throw light on pre-historic migrations of several native tribes, as well as on aboriginal commerce and interchange of arts. Their operations will extend to Puerto Rico and several other Antillean Islands.

THE REV. FATHER JOSÉ ALGUE, director of the Manila Observatory, and his associate, Father José Clos, have arrived at San Francisco on their way to Washington. They wish to arrange for the continuation of the work of the Observatory and the publication of the results by the government.

PROFESSOR A. J. HENRY, who has been for twenty years connected with the Weather Bureau and who is at present chief of the Division of Meteorology, has been appointed to fill the vacancy caused by the death of the late H. A. Hazen.

MR. A. A. HELLER has returned to Puerto Rico to extend his collections made in 1899 for the New York Botanical Garden. He will keep the field during January and February, with headquarters at Mayaguez in the western part of the island.

WE are glad to learn that Professor R. H. Chittenden of Yale University who has been seriously ill with typhoid fever is now better.

WE learn from *Nature* that the Council of the Manchester Literary and Philosophical Society have awarded the Wilde Medal for 1900 to Lord Rayleigh, for his contributions to mathematical and experimental physics and to chemistry; a Dalton Medal (struck in 1864) to Sir H. E. Roscoe, for his remarkable original researches in chemistry, and for his distinguished services to scientific education; and the Wilde Premium for 1900 to Professor A. W. Flux, for his papers on economic questions read before the Society. The presentation of the medals and the premium took place at a special meeting, when Lord Rayleigh delivered the Wilde Lecture for 1900.

M. POINCARÉ has been awarded the gold medal of the Royal Astronomical Society.

IT is understood that Sir John Lubbock, on his elevation to the peerage, has decided to take the name of Lord Avebury, after a property of his in Wiltshire. According to Sir John Lubbock's description in 'Prehistoric Times,' the temple of Avebury, Wiltshire, was the greatest of all so-called Druidical monuments.

M. M. DARBOUX and Moissan have been appointed delegates of Paris Academy of Sciences to the celebration of the second centenary of the Berlin Academy of Sciences.

AT the annual meeting of the Royal Meteorological Society, London, on January 17th, Mr. G. J. Symons, F.R.S., was elected president for the ensuing year.

AT the first meeting of the Académie de Médecine for 1900 the retiring president, Professor Panas, gave his valedictory address, reviewing the important work and communications of the past year. Professor Marey succeeds him in the presidency and Professor Guyon has been elected vice-president.

The annual general meeting of the Neurological Society of London was arranged for February 8th, when it was expected that the president-elect, Dr. A. D. Waller, F.R.S., would deliver an address on the 'Excitability of Nervous Matter, with special reference to the Retina.'

We regret to learn of the death of Mr. John Bernard Stallo, who died at Florence, on January 6th. He was born in Oldenburg in 1823, and came to the United States when he was sixteen years old. Mr. Stallo was a lawyer by profession, had been a judge at Cincinnati, Ohio, and had been minister of the United States at Rome, and had lived in Italy since 1885. He was the author of a volume in the International Scientific Series entitled, 'The Concepts and Theories of Modern Physics,' which is in many ways a remarkable and important work. He was also the author of 'General Principles of the Philosophy of Nature,' and 'Redung. Abhandlungen und Briefe.'

A telegram has been received at Harvard College Observatory from Professor Kreutz, at Kiel Observatory, stating that a comet was discovered by Giacobini at Nice, January 31^d.292 Greenwich Mean Time in R. A. 2^h 57^m 44 and Dec. — 7° 55′.

A committee of the Pan-American Medical Congress has asked the U. S. Department of Agriculture to coöperate with other nations in an investigation of the medicinal flora of the United States, and Secretary Wilson has asked for an appropriation of $10,000 for this purpose.

On the 21st of February the Senate committee on the District of Columbia will hold a hearing on the subject of the anti-vivisection bill now pending before the Senate. This hearing will be attended by leading advocates of vivisection from all parts of the country, as well as by those who favor the pending bill. Dr. W. W. Keen, president of the American Medical Association, has published in the *Philadelphia Medical Journal* an appeal to the medical profession of the United States in regard to the bill. Dr. Keen in his appeal states that the "Bill is speciously drawn to seem as if it were intended only in the interest of prevention of cruelty to animals," that the "real object of the Bill is twofold: first, to prohibit vivisection, and secondly, to aid the passage of similar Bills in all the State Legislatures." He says "that this would seriously interfere with, or even absolutely stop, the experimental work of the Bureau of Animal Industry, and the three medical departments of the Government—the Army, the Navy and the Marine Hospital Service." He therefore appeals "to the entire profession of the country to exert themselves to the utmost to defeat this most cruel and inhuman effort to promote human and animal misery and death, and to restrict scientific research."

The Senate Committee on Commerce, on February 1st, practically decided on a favorable report upon the bill creating a department of commerce, but owing to the desire to change some of the details of the measure, it will not be reported for some time.

At a recent meeting of the Board of Trustees of the University of Wyoming, the herbarium connected with this institution was officially recognized as The Rocky Mountain Herbarium, and Dr. Aven Nelson, professor of botany in the University, was named curator. The object of the herbarium is to make an accessible and serviceable collection of the plants of the Rocky Mountains. The collection will be a general one but plants of economic importance will have special attention. It is especially desired to represent fully forage of all kinds, useful and ornamental trees and shrubs, and herbaceous plants which are of interest to the gardener or are desirable for the decoration of the home grounds. Besides these the parasitic fungi and the fleshy fungi are to be fully represented. The present collection numbers nearly 18,000 sheets. The coöperation of botanists and collectors is requested. Sets of plants collected in the Trans-Mississippi portion of the United States are especially desired as well as co-types or representative specimens of new species from this region. Correspondence concerning specimens and exchanges should be directed to the curator.

Plans are being made for the enlargement of the John Crerar Library, Chicago, which it will be remembered is devoted to scientific works. The Library at present occupies the sixth floor of the Marshall Field building, and a part of the fifth floor is now to be added. A room will be provided for society meetings. The number of accessions to the library during the past year is 12,360, and the total number of books and pamphlets in the library is now 80,000.

MME. MEDVEDNIKOVA, who died recently near Moscow, has left $3,000,000 to charities, chiefly to hospitals and asylums.

THE department of superintendence of the National Educational Association will meet in Chicago on February 27th and 28th, and March 1st. Professor Nicholas Murray Butler will make an address at the first sesson on the 'Status of Education at the Close of the Century.' Other addresses will be made by President Benjamin Ide Wheeler of the University of California, Mr. Walter H. Page, and others. Professor W. O. Atwater, of Wesleyan University, will present a paper on alcoholic physiology and superintendence.

AT a meeting of the Royal Geographical Society held on January 23d, in the theatre of the University of London, Mr. H. J. Mackinder, reader in geography at the University of Oxford, read a paper describing his recent journey to the summit of Mount Kenya, British East Africa. The results of the expedition were a plane-table sketch of the upper part of Kenya, together with rock specimens, two route surveys along lines not previously traversed, a series of meteorological and hypsometrical observations, photographs by the ordinary and by the Ives color processes, collections of mammals, birds and plants, and a small collection of insects.

THE new German Society for Volkshygiene held its first public meeting during January in Berlin. Dr. Boediker took the chair, and there were delegates present from the German Ministry of the Interior, from the municipalities of Berlin and Charlottenburg, and from the government of the Province. Professor Fuchs, rector of the University, and Professor Riedler, rector of the technical high school, were also present, and many medical men of distinction, among them Professors v. Leyden, Jolly, Ewald, Rubner, and Lassar. In his introductory address, the president described the objects of the new Society.

THE New York *Medical Record* gives the following summary of the invasion of the Islands of the Pacific by the plague : In Honolulu, up to January 17th, there had been thirty-nine deaths, one of a white woman and the others among natives and Asiatics. The board of health has burned ten blocks of houses in the plague-infected section. A Red Cross society, formed by some of the ladies of Honolulu, has done most effective work, and the local physicians and clergymen have continually gone among the sick and dying, submitting to voluntary isolation in order to minister to the needs of the sick. In Noumea, New Caledonia, the disease has prevailed since early in December. There were sixteen deaths during the first ten days following the development of the malady. Up to December 23d there had been no deaths among the whites, eight of whom had been infected, but nine Kanakas, two Japanese, and five Tonkinese had died of the disease. The part of the town where the infection first developed has been surrounded with a high galvanized iron fence seven hundred yards long. The principal business houses, official buildings, and the banking and shipping offices are guarded by posses of soldiers. Twenty buildings in the infected quarter of the town were demolished by the health authorities, but, despite all the precautions, the plague has continued to spread, the number of new cases averaging three daily. At Sydney, New South Wales, general alarm is felt in consequence of the arrival of eleven passengers from Noumea, who landed before news of the plague's presence was received. Extraordinary precautions have been taken throughout Australia and strict quarantine is established. In the case of a wharf laborer in Sydney, who was attacked on January 24th, the inoculation was apparently traced to a flea bite. In Argentine Republic the plague is officially announced to exist at Buenos Ayres and Rosario, both of which ports have in consequence been closed.

THE *British Medical Journal* states that the King of Italy has promised to open a hygienic exhibition at Naples in April, and it will remain open until September. The construction of the buildings is being pushed on with great zeal, and funds are assured partly by direct donations and partly by redeemable shares. Several conferences will be held. The most important will be those on the prevention of tuberculosis, and on the promotion of physical education. Amongst the most interesting 'side shows,' will be an exhibition of works of 'Sacred Art.' The Minister of Public Instruction has directed that objects of this description at present located in public museums and buildings shall be lent. There will also be a 'Pompeian Pavilion,' in which will be reproduced the public and private baths of Pompeii and other objects of interest.

THE Medical Society of the State of New York held its 94th annual meeting, at Albany, on January 30th and 31st, and February 1st. We learn from the report in the New York *Medical Record*, that the inaugural address of the president, Dr. W. G. Macdonald, reviewed especially the work of the Society. He said that the efforts of the Society's committee and of the New York Bar Association to improve the status of medical expert testimony had unfortunately resulted in nothing more than a better general understanding of the intricate problems involved. In the opinion of the speaker the legal profession is responsible for the present order of things. Presiding judges could readily remedy existing abuses by excluding medical advocates from the witness box. A voluntary society of men doing expert work could do much to regulate the condition. On the topic of State control of such chronic diseases as tuberculosis and syphilis, the speaker stated that the tendency at present was toward such State control and isolation in sanatoria. The Committee on Legislation reported that two hundred and sixty-five bills of a medical nature had claimed the attention of the committee during the four months' session of the last legislature. The committee on the United States Pharmacopœia, favored the establishment of a bureau of materia medica for the disinterested investigation into the character and value of new drugs, the bureau to be under the authority of the dicennial convention of 1900, subject to the provision that this bureau should report annually. The Society recommended the continuation of the State appropriation for the support of the Pathological Institute, but there was some criticism of its methods.

UNIVERSITY AND EDUCATIONAL NEWS.

THE Regents of the University of California have adopted the policy of giving the professors of the University one year's leave of absence in seven. They are usually to receive two-thirds of the regular salary, but those who have not yet received a leave of absence may receive full salary.

IT is now said that the decision of the Court of Appeals of New York sustaining the will of William Lampson, ends the litigation over his will, so far as any question of law is concerned. The heirs, however, will contest the will on the ground of the incompetency of the testator. The value of the propeerty which is largely real estate is estimated at $350,000 or more.

PRESIDENT LOW of Columbia has been asked to deliver the address at the celebration at Dartmouth College next year of the centennial anniversary of the graduation of Daniel Webster from that institution.

DR. G. A. MILLER of Cornell University was recently elected to membership in the Mathematical Society of France.

M. GABRIEL TARDE, well known for his contributions to psychology and sociology, has been elected to the chair of modern philosophy in the Collège de France.

PROFESSORS Ebner and Schaffner, who have hitherto acted as assistants in the Embryological Institute of the University of Vienna, have been appointed acting directors on the retirement of Professor Schenk.

DR. A. KLAUS, professor of chemistry in the University of Frieburg in Br., has retired on account of ill health.

SCIENCE

FRIDAY, FEBRUARY 16, 1900.

CONTENTS:

MSS. intended for publication and books, etc., intended for review should be sent to the responsible editor, Professor, J. McKeen Cattell, Garrison-on-Hudson, N. Y.

THE VAN'T HOFF CELEBRATION.

A QUARTER of a century has passed since Van't Hoff obtained the degree of Doctor of Philosophy. This event was celebrated on December 22, 1899, in Rotterdam, by his students and a number of guests, including some of the leading men of science. An extra volume of the *Zeitschrift für physikalische Chemie*, containing investigations by those who, at some time, had worked with Van't Hoff, was published and presented to him on this occasion.

What does this mean; why has such an unusual tribute been paid to this comparatively young man?

There is nothing more inspiring to workers in the field of science, than the lives and works of those who are the leaders of modern science. Let us turn to the biographical sketch of Van't Hoff, by Ostwald, which serves as a preface to the 'Jubelband.'

Van't Hoff is the son of a Dutch physician, and was born in Rotterdam, August 30, 1852. He received his early training at a high school in his native city, and at seventeen entered the Polytechnic Institute in Delft. He then studied at Leiden, with Kekulé at Bonn, and with Würtz in Paris. He made the doctor's degree at the University of Utrecht, on the 22d of December, 1874. In 1876 he became docent at the veterinary school in Utrecht, and in 1877 was called to the University in Amsterdam. In 1894 he left Amsterdam to accept a chair of Physical Chemistry at the University of Berlin, which had been founded especially for him.

Van't Hoff's contributions to science fall into three classes ; or we may say, in brief, he has done three things. His earliest work of importance had to do with the spatial arrangement of the atoms in the molecule. In the same year in which he obtained the degree of Doctor of Philosophy, he published a small pamphlet of eleven pages, which is the beginning of all stereochemistry. In the following year it was enlarged to forty-four pages, and published in French under the title, "La chimie dans l'espace." It was translated into German two years later, with an enthusiastic preface by Wislicenus.

The attitude of Kolbe, who utilized his position to belittle not only the work but also its author, is familiar to every one. Indeed, so familiar, that Kolbe's reputation for liberality is not materially increased by the criticism which he offered of this work.

Van't Hoff attempted, in this work, to formulate a rational theory of the arrangement of the atoms in the molecules of certain substances. Let us consider the very simple compound of carbon and hydrogen, CH_4. All the properties of this substance show that it is a symmetrical compound, every hydrogen atom bearing exactly the same relation to the molecule. By what possible geometrical configuration in three dimensions can this be expressed? Evidently by the regular tetrahedron, and by this alone. If we represent the carbon atom as being placed at the center of a regular tetrahedron, and the four hydrogen atoms at the four corners, or in the four solid angles of the tetrahedron, we have a perfectly symmetrical configuration. This was pointed out by Van't Hoff, and has come to be known as the 'theory of the tetrahedral carbon atom.'

One application of this theory will serve to show how it has been of service in advancing our knowledge of organic substance. A comparatively large number of compounds were known, which, in the liquid state or in solution, would rotate the plane of polarization when a beam of polarized light was passed through them. In some cases the rotation was to the right, in other cases to the left. Further, it was very probable that for every substance which rotates the plane of polarization in one direction, there is a substance of the same composition rotating the plane in the opposite direction. How could these facts be interpreted in terms of the theory of the tetrahedral carbon atom?

Van't Hoff pointed out that every one of these so-called optically active substances contains a carbon atom in combination with *four different atoms or groups.* It is only when the four atoms or groups at the solid angles of the tetrahedron are all different, that two configurations are possible. If any two of the atoms or groups are the same, it is impossible to construct two tetrahedra which shall differ from one another. But if the four atoms or groups are all different, two tetrahedra can be constructed which bear the relation to each other of an object and its image in a mirror. These two configurations represent the two substances which have the same composition, but are optically active in opposite senses. When this theory of 'the asymmetric carbon atom' is applied to all of the facts known concerning optically active substances, we find that out of the seven hundred optically active compounds, there is only *one* which may be an exception to it. But this substance is so complex that its constitution is far from settled.

This is but one application of the theory of the tetrahedral carbon atom. This theory has thrown entirely new light on the meaning of isomerism in organic chemistry. By means of it many cases of isomerism have been satisfactorily explained, whose meaning was entirely shrouded in darkness before the theory was proposed. By means of this theory large numbers of isomeric substances have been predicted, and many of these have already been discovered.

The theory of the space relations in carbon compounds has led directly to a theory of the stereochemistry of compounds containing nitrogen, and some extremely interesting and important work has been done in the last ten years upon this problem. Under the guidance of these new conceptions entirely new classes of compounds have been brought to light, and cases of isomerism discovered whose existence could never have been suspected, had not the theory of the tetrahedral carbon atom been proposed.

If we look over the field of organic chemistry in a broad way, it is not too much to say that the most important advances which have been made in organic chemistry in the last quarter of a century, have centered closely around this theory of the tetrahedral carbon atom. If we think only of the applications of the theory which have been made by Wislicenus, Hantzsch, and Emil Fischer, we shall see that it has contributed more to the advancement of our knowledge in this field, than any suggestion since Kekulé proposed the benzene hypothesis which bears his name.

In 1878 Van't Hoff published a book which is but little known, and which has had but little direct influence—'Ansichten über die organische Chemie.' But this book is closely connected with his second great contribution to chemistry.

He attempted to develop a side of organic chemistry which had hitherto received but very little attention. What would be the effect of different masses of one substance when allowed to act on a given mass of another substance? This quantitative side of organic chemistry had been either entirely neglected, or dealt with only as affecting the yield which would result from the reaction. Van't Hoff applied the law of Guldberg and Waage to organic reactions, and pointed out the importance of the study of the dynamics of reactions. He studied the velocity with which given reactions would take place, and the conditions under which equilibria in chemical processes were established. His first results were published in his 'Études de Dynamique Chimique' in 1884.

The work is not simply experimental. Indeed its theoretical side is of the very highest importance, since it was shown here that we can apply thermodynamics to chemical processes. The whole science of chemical dynamics and statics has acquired an entirely new meaning in the light of this work, which has contributed more to place organic chemistry on a quantitative basis, than any investigation which has ever been published. This work was greatly enlarged and published in 1896, under the title 'Studien zur chemischen Dynamik,' by Van't Hoff and Cohen.

The second epoch-making work of Van't Hoff is much less widely known than the first. This is due in part to the comparative complexity of the processes dealt with, and in part to the rigorous mathematical treatment which he applied to them. But I believe that time will show that the *Chemical Dynamics* of Van't Hoff is vastly more important than his *Stereo-chemistry* in placing chemistry upon that exact mathematical basis, toward which all branches of natural science tend, as our knowledge of the phenomena becomes deeper and deeper.

The third great work of Van't Hoff still remains to be considered. I refer to the relation which he showed to exist between the pressure of gases and the osmotic pressure of solutions. The genesis of this idea has been furnished us by Van't Hoff himself, in the lecture which he was invited to deliver before the German Chemical Society in 1894. As we have seen, he was early occupied with the study of the position of atoms in space. From this he was led to study the velocity of reactions and the conditions of equilibrium in chemical processes. But the problem of affinity was closely connected with that of equilibrium. As an example of affinity he studied the attraction of salts for their water of crystallization. He found this to be very small and adds: "I had the impression that even the weakest chemical forces are very large. * * * The question arose whether it is not possible, in simpler cases, to measure the attraction for water more directly; and for this purpose the aqueous solution is the simplest conceivable—much simpler than the compound containing water of crystallization. Coming from the laboratory with this question in mind, I meet my colleague De Vries, and his wife. He was just at that time carrying out osmotic investigations, and he told me about Pfeffer's determinations."

Van't Hoff was thus introduced to the work of Pfeffer, in which the latter had measured the osmotic pressure exerted by aqueous solutions of a number of substances, when separated from the pure solvent by a semipermeable membrane, through which the solvent, but not the dissolved substance, could pass. Van't Hoff observed from Pfeffer's results, that the osmotic pressure exerted by any substance at a constant temperature is proportional to the concentration of the solution, and saw in this an analogy to Boyle's law for gas-pressure. The gas-pressure of a gas is proportional to the concentration of the gas. Having found this one relation between osmotic pressure and gas-pressure, he tested other laws of gas-pressure by the osmotic pressure of solutions, and found that the law of Gay Lussac for the temperature coefficient of gas-pressure, applies also to the temperature coefficient of osmotic pressure. These two laws of gas-pressure might apply to the osmotic pressure of solutions, and still the absolute value of the two pressures be very different.

The fundamental question still remains: Is there any close relation between the actual pressure exerted by a gas, and the osmotic pressure exerted by a solution containing the same number of dissolved particles in a given space as there are gas particles; temperature, of course, being the same in the two cases? Van't Hoff discovered this remarkable fact; that the gas-pressure exerted by a gas particle is *exactly equal* to the osmotic pressure exerted by a dissolved particle, concentration and temperature being the same in the two cases; space playing a rôle with gases, which is analogous to that of the solvent with solutions. In a word, Avogadro's law for gases applies directly to the osmotic pressure of solutions. The three fundamental laws of gas-pressure thus apply directly to the osmotic pressure of solutions.

This relation is, in itself, of course very interesting. But why is it referred to as of epoch-making importance? Partly because of the new light which it throws on the whole problem of solution. We can apply thermodynamics freely to gases, and since the laws of gases apply to solutions, we can use thermodynamics in dealing with solutions in the same sense as in dealing with gases. And partly because it is the forerunner of the most important theory which has been proposed in chemistry or in physical chemistry for the last half-century.

We have stated that the laws of gas-pressure apply to the osmotic pressure of solutions, and this is true for solutions of certain classes of substances. It holds for all of those substances which, when in solution, do not conduct the current and therefore do not undergo decomposition. These substances are called non-electrolytes. But this relation does not hold for any substance which, when dissolved in water, conducts the current; and this class, called the electrolytes, includes all the acids, all the bases and all the salts. The exceptions to Van't Hoff's generalization are quite as numerous as the cases which conform to it; and the former are even more interesting than the latter.

To account for these exceptions it was assumed that in aqueous solutions of acids, bases and salts, the molecules are more or less broken down or dissociated into ions; the amount of the dissociation increasing with the dilution of the solution. An ion is an atom, or group of atoms, charged either positively or negatively. This suggestion, which has been placed upon its present quantitative bases by Arrhenius, is the direct outcome of the analogy between the laws of gas-pressure and of osmotic pressure, pointed out by Van't Hoff. The theory of electrolytic dissociation thus originated.

The importance of the discovery of the applicability of the gas laws to osmotic pressure can now be seen, when we consider that this relation, together with its direct consequence, the theory of electrolytic dissociation, are the two corner-stones of modern physical chemistry. Indeed, the physical chemistry of to-day has grown up almost entirely around these two conceptions. It is from these two generalizations, directly, that Nernst has calculated the electromotive force of primary cells, and has furnished us with the first satisfactory theory of the action of such cells. Still further, he has gone into the cell itself and analyzed its action, calculating the amount of potential which exists at the several sources of potential, and has shown that molecules as such have nothing to do with the action of the primary element; only the ions into which the molecules dissociate coming into play.

These generalizations have, on the other hand, entirely revolutionized our conception of chemical activity. We now know that a large majority of the chemical reactions with which we have to deal, take place entirely between ions; atoms and molecules as such, playing no rôle whatsoever in the reaction. Indeed, we have already reached a stage where it is safe to say that very few chemical reactions are other than ionic; and very recent work makes it more than probable that atoms and molecules are entirely incapable of entering into any chemical reaction. The chemistry of atoms and molecules is thus rapidly giving place to the chemistry of ions. But space will not allow further applications of these all-important generalizations.

In addition to these three monumental pieces of work, any one of which would secure permanent fame for its author, Van't Hoff has made a number of important contributions to science. His paper on *Solid Solutions* has called attention to an interesting and important class of phenomena, which had never been in any sense connected with solutions. And the activity which characterized the earlier years of his life still manifests itself to an unusual degree. This is seen in the number and nature of the investigations which are coming from his laboratory in Berlin, and in the volumes which are appearing from his pen.

If we take into account the nature and significance of the entire work of this remarkable man, it seems quite safe to predict that he will be regarded in the future as occupying a place in the same rank with men like Pasteur and Virchow, Helmholtz and Kelvin.

The celebration in Rotterdam in honor of the first twenty-five years during which Van't Hoff has worked for pure science, is a memorable event especially in the history of modern physical chemistry. There were present such men as Ostwald, Roozeboom, Lobry de Bruyn, Spring, Lorenz, Goldschmidt, Du Bois, Bredig, Ikeda, Dawson, De Hemptinne, Holleman, Jorissen, Reicher, Var Laar, Wind, Cohen, Meyerhoffer, and many others; including a large number of his students and friends.

The Burgermeister of Rotterdam made an address of welcome, which was followed by a second address by Ostwald. Telegrams were received from all parts of Europe, and cablegrams from America, Japan and Java; extending congratulations to Van't Hoff. Cohen, who was for a long time Van't Hoff's assistant in Amsterdam, prepared and presented to Van't Hoff a biographical sketch of the life of the latter, while Meyerhoffer presented the 'Jubelband.'

A word in conclusion in reference to this volume. Some two years ago a printed slip was sent to all who had worked with Van't Hoff, inviting them to contribute an original investigation to a volume which would be published and presented to Van't Hoff on the twenty-fifth anniversary of the day on which he received his degree of Doctor of Philosophy. A short time before the volume was published we were notified that it would appear as an extra volume of the *Zeitschrift für physikalische Chemie.*

It has thus appeared as volume 31 of this Journal and is known as the 'Jubelband für J. H. Van't Hoff.' Outside of its personal interest to those who have sent contributions, and of its scientific value, it has a linguistic interest. It contains papers in four languages: German, English, French, and Dutch. The papers are evidently published in the languages in which they were written by the contributors. The volume contains twenty-six papers in all, most of them from Germany and Holland, but there are a few from England and two from America.

Thus was celebrated the first quarter of a century of activity of this most brilliant man. The history of men of science has few such records.

Harry C. Jones.

Chemical Laboratory,
Johns Hopkins University,

THE MEETING OF NATURALISTS AT CHICAGO.

In response to a call issued December 8, 1899, and signed by Professors C. R. Barnes, H. H. Donaldson, S. A. Forbes, W. A. Locy and Jacob Reighard, about thirty naturalists of the Central States met at the Hull Biological Laboratory, on Thursday and Friday, December 28th and 29th. Among those present, in addition to the Chicago naturalists, were Professors Burrill, Kofoid and Smith, of the University of Illinois; J. G. Needham, of Lake Forest; H. V. Neal; of Knox College; Birge, of Wisconsin; Lee, Nachtrieb and Sigerfoos, of Minnesota; H. L. Osborne, of Hamline University; Nutting, of Iowa; Eigenmann, of Indiana and Reighard and Jennings, of Michigan. Professor Donaldson presided at all the meetings and at the dinner.

Thursday morning and Friday morning and afternoon were devoted to the reading of papers. Twenty-five titles were announced; but five of these were omitted through the absence of the naturalists who announced them or through lack of time. Thursday afternoon was devoted to a discussion on 'Methods and Results of Limnological Work.' Professors Birge and Kofoid opened the discussion, in which Professors Reighard, Nachtrieb, Eigenmann, Osborn and Davenport also took part. The papers of Professors Birge and Kofoid follow this report. On Thursday evening a dinner was held at the Quadrangle Club, and was attended by thirty persons. After the dinner the question of organization was considered. Since the American Society of Naturalists simultaneously meeting at New Haven had neither rejected nor adopted the proposition that a branch or section of the American Naturalists should be authorized to hold meetings in the Central States, but had appointed a committee to consider the matter, it was decided not to organize. A committee consisting of Professors Rieghard, Locy and Nachtrieb was instructed to nominate five naturalists who should have charge of all arrangements for a second meeting and should report at that meeting recommendations for a permanent organization and for the establishment of relations with the American Society of Naturalists. The committee subsequently elected consists of Professors Birge, President; Barnes, Lee, Nutting and Davenport, Secretary.

Abstracts of the papers read at the meeting follow:

Townet collecting at Cold Spring Harbor, Long Island. CHAS. P. SIGERFOOS.

During the summers of 1898–99 fairly complete records of townet collecting were kept at the Laboratory of the Brooklyn Institute. Cold Spring Harbor is so far from the open sea that larval and other transitory pelagic forms are never, perhaps, swept in by winds and tides from the outside. This is an advantage in many cases, because it enables the collector to say that certain forms found there live, thrive and breed locally.

As elsewhere, the day collections are less varied and abundant than those made in the night-time. In the former are present the medusæ of various hydroids (*Podocoryne*, *Bougainvillea*, *Perigonimus*, *Obelia*, etc.); ctenophores (*Mnemiopsis*) in all stages; starfish larvæ; pelagic fish eggs; and many other forms found less frequently or especially at night. In the night-time there are present, in addition to the above, great numbers of copepods (mostly of a species of *Acartia*), many of its individuals parasitized by *Apoblema*; larvæ, in various stages, of *Squilla*, decapods and other crustaceans; adult *Diastylus*, *Mysis*, *Gammarus*, etc.; the larvæ of various molluscs (*Ostrea*, *Crepidula*, *Bulla*); and many other forms found less frequently. One of the most interesting finds consisted of a few specimens of tornaria larvæ, apparently belonging to an undescribed species of *Balanoglossus* found at Cold Spring Harbor.

On the motor reactions of Flagellata and Ciliata. H. S. JENNINGS.

Previous work had shown that the aggregations of Paramecia in certain chemicals, in regions of optimum temperature and the like, as well as their avoidance of certain agents, are due to a motor reflex of essentially the same character as the motor reflexes so well known in higher organisms. This reflex consists in swimming, when stimulated, toward a structurally defined end and turning toward a structurally defined side, whatever the nature or position of the stimulating agent. The paper presented a study of a number of flagellates and ciliates, to determine whether such a motor reflex is common. It showed that *Chilomonas*, *Euglena*, *Loxophyllum*, *Colpidium*, *Microthorax*, *Dileptus*, *Loxodes*, *Prorodon*, *Stentor*, *Spirostomum*, *Bursaria*, *Oxytricha* and some others respond to many stimuli by a reflex essentially similar to that of *Paramecium*. It seems probable therefore that the so-called chemotaxis, thermotaxis, tonotaxis, and the like of these groups of organisms are in general, as in *Paramecium*, produced through such a reflex. Whether this reflex plays a part in phototaxis, electrotaxis and geotaxis has not been shown. The paper showed also that many of these organisms are much more sensitive at their anterior ends than elsewhere on the body, and brought out a number of facts in regard to the reactions to localized stimuli.

Notes on the occurrence of Uroglena in the Lafayette water supply. SEVERANCE BURRAGE, Purdue University.

Uroglena is one of the organisms that has become of interest to engineers and biologists on account of the disagreeable oily or fishy taste and odor imparted by it to water supplies. It is apt to occur in the clearest and purest waters. The Lafayette supply is derived from driven wells in the bed of the Wabash river, and before reaching the reservoir is a most excellent and inoffensive water. This reservoir, however, being uncovered, furnishes an admirable opportunity for the growth of any organism. It seems probable that several small ponds—so-called lakes—that lie within a few hundred feet of the reservoir, serve as culture beds for the *Uroglena*, and the reservoir may become inoculated by means of birds and other agents. *Uroglena* may be found in some one of these ponds at almost any time. The Lafayette reservoir was infested with this organism in the late summer and early fall of 1896, and it has reappeared quite regularly ever since, in the warm weather. The species of *Uroglena* occurring here corresponds fairly well with *U. Americana* (Calkins), as described in Massachusetts State Board of Health Report, 1891.

It was not the purpose of the paper to bring out any new facts in regard to the organism *Uroglena*, but merely to record its rather regular appearance in Lafayette.

Remarks on a series of wax-models, illustrating cleavage stages in Crepidula. Thomas G. Lee.

The models shown were made by Mr. B. Eric Dahlgren, one of Dr. Lee's students, at his laboratory at Minneapolis. Mr. Dahlgren seems especially fitted to do this sort of work, if there is a demand for it.

Spermatogenesis in Hybrid pigeons. M. F. Guyer.

Hybrid pigeons exhibit several abnormalities in spermatogenesis. These are most marked in the sterile hybrids. In such, the first thing to strike the attention is a curious bead-like varicosity about the middle of the spermatozoön head. In the development of such spermatozoa the nucleus does not elongate completely, as it does normally, to form the head; consequently, at one point there remains a sort of vesicle corresponding in position to the original nucleus before the ends pushed out to form the long head. Some of the sterile birds showed also a marked degeneration of the germinal cells. In some cases no spermatozoa were matured and many of the cells had degenerated. Often deeply-staining masses of protoplasm each with a large central vacuole were present. In both sterile and fertile hybrids there was much variation in cell division. Inequalities in chromatin distribution were common and multipolar spindles, abundant. The nuclei of the spermatogonia contained sixteen chromosomes, which is the regular number. In normal primary spermatocytic there are eight large ring chromosomes, each apparently being equivalent to two of the spermatogonial type, but in the hybrids there were often more than eight. Sometimes there were as high as sixteen small rings, in which case a doubling of the chromosomes had evidently not occurred. When sixteen chromosomes were present in the spermatocytes they were usually located on two spindles, eight to a spindle. Frequently both large and small rings were present. These peculiarities in chromosome formation may point perhaps to a tendency in the chromatin of each parent species to retain its individuality. If such is the case, then in those cells with two spindles each bearing eight chromosomes, it is evident that after division, some of the new cells will have chromatin from only one of the original parent species and some, from the other. Some of the spermatozoa, therefore, will bear chromatin from one only of these species. It is a well-known fact that the offspring of hybrids are extremely variable, a portion of these variations being usually in the form of reversions to one or the other of the parent species. The possibility presents itself then, that this reversion may be due to the persistence of the chromatin of only one species in one or both of the germ cells. Carrying the conception still further, the other variations in the offspring of hybrids may be due, perhaps, to the varying proportions of the chromatin of each species in the mature germ cells.

The egg of the Stichostemma. C. M. CHILD.

During the autumn of 1899 a species of *Stichostemma*, probably *S. asensoriatum* Montgomery, was found in great abundance in a park lagoon in Chicago. In this small fresh-water nemertean, the gonads occupy the position usual in nemerteans, *i. e.*, between the diverticula of the intestine. The animal is hermaphroditic and probably more or less completely protandric, though spermatozoa are often found in the same gonads with ripe eggs. The gonad is in the form of a follicle, which is lined with the germinal syncytium. The portion of the syncytium which is to form the egg, containing one nucleus, bulges out into the cavity of the follicle and grows in size so that the follicle is filled. It remains attached to the remainder of the germinal mass by a pedicle, and yolk spheres are formed not only within the limits of the oöcyte itself but also in the protoplasm about the pedicle. As the oöcyte grows, the greater portion of the germinal protoplasm appears to pass into it and all or nearly all of the germinal nuclei disappear leaving a single oöcyte in the gonad. Sometimes two oöcytes instead of one are formed in one gonad. The growing oöcyte forms a membrane about itself, but the stalk remains until the egg is laid, when it is broken off and the membrane, which swells rapidly under the action of water, closes over this portion of the cell also. Thus the oöcyte does not become a distinct cell until the moment of laying.

The pore of the gonad is apparently not preformed, appearing at the time of laying. As it is very small the egg is greatly deformed in its passage, but its protoplasm is so fluid that it flows out easily, in a fine stream, all except the nucleus, which often appears to block the way for a moment and then pops out suddenly. After laying the egg soon assumes a spherical form and the membrane swells to a considerable thickness. Eggs are laid normally in strings somewhat less in length than the body of the worm, and containing two rows of eggs in a considerable amount of slime secreted by the skin, and attached to plants, etc.

Self-fertilization may occur (probably occurs normally in many cases) and is followed by normal development. Almost immediately after fertilization the whole surface of the egg becomes roughened in consequence of ectoplasmic activity, and soon accumulations of liquid appear between the egg and the membrane. Various changes of form occur during the formation of the two polar bodies, and, the vitelline membrane being absent, amœboid processes of the ectoplasm appear at many points. Soon after their formation the polar bodies begin to enlarge and become transparent, and before the first cleavage is completed they have usually disappeared. In the manner of their degeneration they resemble very closely injured or unripe eggs which die in the water. These increase in size very rapidly and become vacuolated and soon the yolk becomes liquid and disappears.

Just before and during the first cleavage pseudopodia-like outgrowths of the ectoplasm are abundant in the region of the cleavage-furrow. The ectoplasm is clearly continuous between the cells.

In the resting two-cell stage, again in the four-cell stage, and between adjacent cells in subsequent stages temporary cavities appear which are filled with liquid. These increase in size and finally collapse, often opening distinctly to the exterior. The next division begins almost immediately after their collapse. The excretion of fluid during maturation and fertilization, the tendency to vacuolation of the protoplasm observable in the polar bodies and injured eggs and the accumulation of fluid in temporary intercellular cavities during cleavage are probably, as Kofoid suggests concerning similar phenomena in pulmonates, etc., connected with life in fresh water. The cleavage is spiral.

Concerning Cotylogaster occidentalis sp. nov. Preliminary notice. W. S. Nicherson.

An American representative of the trematode genus *Cotylogaster* occurs in the Mississippi valley parasitic in the 'sheepshead.' The animal is from 8–10½ mm. long. The anterior proboscis-like part of the body is terminated by a five-lobed disk surrounding the mouth. The ventral surface bears a compound sucker composed of from 132–144 acetabula of which from 31 to 34 form a median longitudinal row of transversely elongated grooves; the remaining 100–110 are in a single row surrounding the median series. These are rounded or elliptical in outline and not definitely arranged with respect to the members of the median row. Marginal organs are present.

From the dorsal surface near the posterior end rises a broad conical elevation. The excretory pore is at the base of this cone between it and the posterior margin of the sucker. The genital aperture is median, in front of the margin of the sucker. A penis is lacking: the testes are two in number posterior to the ovary. The ovary is smaller than the testes and on the left of a median plane. The shell gland is anterior to the ovary, diffuse. The vitellaria are a pair of elongated laterally placed cords of tissue. The eggs are numerous, spheroidal, destitute of yolk cells. When discharged they contain a fully formed embryo with unforked intestine and simple subterminal sucker at posterior end. The body of the embryo is covered in part by a simple epithelium bearing distinct tufts of cilia.

Studies in Earthworm Chlorogogue. W. J. Rice. Read by title.

A demonstration of slides illustrating the Compound Oösphere of Albugo bliti, as published in the Botanical Gazette, September and October, 1899. F. L. Stevens.

The simultaneous mitoses of the oögonial nuclei, the multinucleate oösphere and antheridial tube, the extrusion of many male nuclei into the oösphere, the fusion of the male and female sexual elements in pairs to form about fifty fusion nuclei as well as the new cell organ, the *coenocentrum* were abundantly illustrated by slides. The peculiar feature of this work lies in the fact that while this species presents a compound oösphore and a multiple fertilization, other related species seem to show only a simple oösphere and a simple fertilization.

Gametes and Gametangia of the Phycomycetes. B. M. Davis. Read by title.

Suggestions toward a classification of plant societies based on topographic development. H. C. Cowles. Read by title.

The early stages of development of ventral nerves in Cyclostomes and Selachians. H. V. Neal, Knox College.

Problem—Is there a difference in the modes of development of ventral nerves in the lower and the higher vertebrates? Investigators differ in their results. Observations on embryos of Squalus and Petromyzon preserved and stained by the raw Roth-Pyrogallic acid method have given some positive results, while such methods as the Golgi, Gold Chloride, Corrosive Sublimate, Palladium Chloride and others fail in the early stages when the nerves are first formed. The raw Roth-Pyrogallic acid method is advantageous in staining deeply cell boundaries and axis cylinder processes in early stages. The results obtained by the use of this method are: 1. Ventral nerves in Squalus and Petromyzon embryos arise primarily as axis cylinder processes of cells lying in the ventral horn of the neural tube. 2. There are secondarily added to these processes cells from two sources: (*a*) cells which have migrated out from the neural tube in the region of the root of the nerve; and (*b*) cells from the mesenchyma through which the nerve passes. At first these cells take a peripheral position with reference to the bundle of axis cylinder processes (= nerve fibers), but in later stages they migrate into the midst of these processes. 3. The cells thus added secondarily to the nerves do not form nerve fibers as has been held by several investigators, but form simply the primitive or Schwann's sheath. The nerve fibers are from their beginnings the processes of cells lying in the ventral wall of the neural tube as stated above. The mode of development of the medullary sheath has not been determined.

Thus the ventral nerves of these Anamniote forms differ in their development from the same nerves in Amniota only in deriving some of the sheath cells from the neural tube. The sheath cells in Amniota appear to be derived wholly from the mesenchyma (His, Kölliker and others).

The conclusions of Balfour, von Wijhe, Dohrn, Beard, Kupffer and others, that cells migrate from the neural tube into the ventral nerves of Amniote embryo is thus confirmed. The inference that these cells form the nerve fibers is not correct.

On the existence of accessory optic vesicles, based on new observations. W. A. Locy. Read by title.

New observations on the primary segments of the vertebrate head. Charles Hill.

This was presented by Dr. Locy.

The development of the adhesive organ and hypophysis in Amia. Jacob Reighard. (In conjunction with Miss Phelps and Mr. Mast.)

An account of the development of the adhesive organ appeared in the report of the New York meeting (1898) of the American Morphological Society, published in Science. The hypophysis develops as an ectoblast thickening connected with the anterior neuropore and lying, in early stages, between the neuropore and adhesive organ. Its subsequent history does not differ essentially from that described for other vertebrates by Haller. It is at no time connected with the entoblast, and unlike the hypophysis of Acipenser, does not, therefore, afford support to Kupffer's interpretation of the hypophysis as a paleostome.

Exhibition of figures for a Normentafel of Amia with an account of methods of photographing the embryo. Jacob Reighard.

The method consists in the use of a long focus lens (80 mm. projection lens of Leitz), together with a long camera—the large photomicrographic camera of Zeiss—attached to the wall vertically. This arrangement allows of great focal depth, together with a magnification of 10–20 diameters. The microscope stands on a base-plate provided with leveling screws. Focusing at a distance is accomplished with a device which works the coarse adjustment. Reflectors for regulating the intensity of the shadows and a means of marking the embryo in order to obtain a sharp focus were described.

The breeding habits of Amia. Jacob Reighard.

The nests are premeditated structures and are prepared sometime in advance of spawning by the male fish, by biting or tearing away the bottom vegetation. They are not accidental, or mere concomitants of the act of spawning. They may be near or remote from one another according to the character and extent of the available bottom. Spawning is intermittent and usually covers a period of several hours.

Notes on a Dakota Axolotl. H. L. Osborne.

A new *Axolotl* was found in March, 1899, in Amenia, North Dakota, an occurrence farther north than heretofore known. The body proportions are those of an *Amblystoma.* Its total length is 312 mm. It possesses the following larval characters different from previously known *Axolotls*: (*a*) a dorsal fin beginning on the level of the second body ring, 8 mm. high, running around the abdomen to the cloaca; (*b*) a smooth area of the skin on each side of this in the dorsal region; (*c*) a skin beyond the smooth area in the trunk region minutely warty-roughened, and marked with scattered circular dark spots; (*d*) eyes located one-fifth of the distance from the angle of the mouth to the origin of the third gill; (*e*) the longest of the three gills as long as the head; (*f*) the gills all broadly spatulate and flattened and the margin divided distally. The following characters of the adult are present: (*a*) all the four limbs are completely formed; (*b*) the lungs are fully developed; (*c*) the oviducts are much enlarged and filled with eggs ready for deposition. Characters of the skin, the size and form of the gills distinguish it from either the Mexican form or from the *Siredon lichenoides* of Baird and Girard from New Mexico.

The degeneration of the eyes of the cave Salamanders. C. H. Eigenmann.

Will be published shortly in full in Science.

The arrangement of the single and twin cones in the retina of fishes. C. H. Eigenmann.

Will be published shortly in *The American Naturalist.*

Notes on the Natural History of Polyodon. C. A. Kofoid.

In the Illinois River and its adjacent waters, *Polyodon* is pelagic in habit. Its food is typical plankton, chiefly Entomostraca and the larger Rotifera and Protozoa, with no evident admixture of bottom rubbish or sedentary organisms. In swimming the mouth is held wide open, without the rhythmical respiratory movements common in most fishes, though it is occasionally closed energetically. The plankton is thus strained from the water by the long gill-rakers, and *Polyodon* is a living plankton net. The fish was never observed to use the bill to stir up the bottom or in any mechanical way. It quickly perceives plankton or ground fish added to the water of the tank, and, when feeding, circles repeatedly over the same path, at times dragging the lower fins upon the bottom. The bill isabundantly supplied with sensory structures and serves as an expanded sense organ and not as a mechanical aid in feeding.

On Platydorina caudata. C. A. Kofoid.

This new genus of the Volvocidae has been found in the Mississippi, Illinois and Wabash basins in summer and fall months. It consists of a plate of 16 or 32 similar biflagellate cells arranged in a horse-shoe shaped cœnobium, which bears at its posterior end 3 or 5 tails formed of the matrix and sheath. The two faces are exactly alike, alternate cells upon either face presenting the flagella to the surface. The plate is slightly twisted in a left spiral and the rotation of the colony in locomotion is predominantly from right over to left. The polarity of this genus is the most pronounced in the family being structural as well as physiological. The two transverse axes are also established though their poles are not differentiated. Asexual development is similar to that of *Eudorina* with a subsequent flattening of the ellipsoidal cœnobium and an intercalation of the cells of the two sides. Sexual development not known.

Variation in the sea anemone Sagartia Luciæ. GERTRUDE C. DAVENPORT.

Sargartia Luciæ is conspicuously marked by a varying number of orange colored bands which run longitudinally. These orange bands were counted in 751 individuals at Cold Spring Harbor. Their number varied from 0–20. The largest proportion had 12 stripes. Secondary maxima occurred at 8, 4, 1 and 16. Longitudinal division was observed in which the twelve stripes were apportioned to the two resulting individuals as follows: 9–3; 4–8; 5–7. Also such divisions as 3–3; 7–1 were noted. Hence the variation in the number of stripes is dependent upon fission. Division, so far as observed, was aboral-oral and was usually accomplished within of 24 hours. By feeding to repletion, division already begun could be delayed, even apparently prevented. When cut longitudinally into halves regeneration was rapid. Even small fragments artificially obtained reproduced normal individuals. Normal division was observed only in diglyphic types. Monoglyphic individuals are plentiful and occur as the result of division of diglyphic forms. Basal budding and fragmentation are believed to be very common method of multiplication of this species.

Variation studies on Pectinatella magnifica. C. B. DAVENPORT.

The number of spines on the statoblasts of *Pectinatella* from Chicago was counted in over 800 cases. The law of distribution of frequencies was deduced by quantitative methods. The skewness is positive, that is there is an excessive tendency toward large numbers. This fact of variation in the form-unit agrees with the fact that the other races of *Pectinatella magnifica* and the other species of the genus have a larger modal number of spines. The ontogenetic causes of the variation and of abnormalties was considered.

C. B. DAVENPORT.
Secretary.

SOME OF THE PROBLEMS OF LIMNOLOGY.*

IF the object of science is to correlate and state the results of observation in such a way as to produce mental economy, it can hardly be said that limnology has developed very far as a science. It is certainly still true that much of our knowledge regarding lakes is in that condition of detailed statement whose mastery involves great mental exertion. Through this stage all sciences have passed and signs are not lacking that limnology will soon reach the position now occupied by older branches of biological science. To secure this result the student of lake life must attempt to solve problems rather than merely to state facts.

Two classes of problems present themselves to the limnologist: the first, scientific; the second, practical. The first comprises the problems raised by the study of the lake as a unit of environment. The second class concerns itself with the question of the lake as a unit of economic production. The answer to the practical question depends on the correct solution of the scientific problems.

In attempting to solve these problems the limnologist finds himself constantly hampered by the lack of knowledge through which he may interpret the results which he reaches. The acquirement of this knowledge seems to me the first and most necessary step toward bringing exactness and comprehensiveness into our views of lake biology. We count the constituents of the plankton, but are not able to state the significance of the results which we reach. Laborious and slow as the process of counting is, I see no escape from the conclusion that it will remain for a long time the only exact way of ascertaining the facts regarding the assemblage of plants and animals which constitute the plankton. For the

* Address in opening discussion on 'Methods and Results of Limnological Work,' at the meeting of Naturalists at Chicago, December 28, 1899.

interpretation of these results more knowledge is necessary. I shall content myself with pointing out a few directions in which this interpretative knowledge must be gained, if the results of observation are to be of real scientific value. First in importance I should place the knowledge of the chemistry of the plankton, from which its possible nutritive value can be learned. The unit system of counting, as advocated by Whipple, is undoubtedly a great advance on mere enumeration, but the units thus employed are not even units of mass, much less units of chemical composition. The difference in the amount of ash between diatoms and crustacea, not to speak of other differences, is so great that no direct comparison, however exact, of cubic contents can teach us the significance of the two groups in the lake's plankton. Chemical analyses only will do this and these must be be stated both in terms of bulk of the centrifuged or settled plankton, and in terms of the average individual plant or animal, as determined by counting. Every limnologist, therefore, should be careful to avail himself of the opportunity presented by the appearance of a monotypic plankton to collect it in sufficient quantities for analysis. I have myself to confess that I have neglected three opportunities of collecting *Daphnia hyalina* in these large quantities. Similar opportunities have no doubt been neglected by many of us, but the necessity of this information is so pressing that I am sure we must all agree in placing it first on the list of desiderata.

It may be possible to collect the ordinary plankton in large quantities and to separate it into its constituents more or less completely by means of one of the centrifugal milk separators. The difference in density between the diatoms, the cyanophyceæ and the crustacea is so great that there ought not to be any serious difficulty in separating the plankton into at least three groups. So far as I am aware, no experiments have been made in this direction, but the work must be attempted and in some way or other we must secure single groups, or, if possible, single species of plankton plants or animals in quantities sufficient for chemical analysis, or our results will continue to suffer from their present indefiniteness.

A second line of investigation which demands much study concerns the biological significance of the constituents of the plankton, especially of the plants. Many observers have noted that certain algæ are eaten more freely by the crustacea than are others, yet no such careful and continued observations have been made as to enable us to make any general statements on the subject. Evidently, however, this work must be done, or even the chemical knowledge gained by analysis will fail to disclose the real interrelations of the plankton plants and animals.

A third point of equally great importance concerns our knowledge of the chemistry of the water of the lakes and of its gaseous contents as related to the plankton. Many waters have been analyzed, yet few or no attempts have been made to correlate these analyses with the nature and abundance of the several plankton species. Still more conspicuously is this true of gas analyses. We suppose, for instance, that in certain lakes the accumulation of the products of decomposition in the deeper waters prevents the animals of the upper regions from descending into the cooler waters of the lake, yet we are at present entirely ignorant of the nature of these products, whether they are gaseous or other, and of the way in which they are able to affect so powerfully the biological conditions of the sub-thermocline. Numerous similar questions are pressing for solution.

A fourth class of questions comprises those raised by the relation of the littoral area to the limnetic region of the lake.

We may be sure, however, that these questions will be very slowly answered, since they open the most complex questions of lake life and those most difficult of solution. We know enough already to be confident that general statements regarding the relation of littoral and limnetic regions are very unsafe. It is true that lakes with steep banks are plankton-poor, yet it does not follow that lakes with large littoral areas are correspondingly rich in plankton. It certainly is not true that lakes are poor in plankton in proportion to their depth, so that even these most simple relations between the shore regions and the deeper water require careful and extended study in order that any safe conclusions may be drawn.

I have contented myself with pointing out a few of the directions in which limnology needs to move if the stock of facts which limnologists are accumulating is to receive an adequate interpretation. In order that such a result may be reached in the future, it is necessary for the student of lakes to propose to himself definite questions and to work as definitely toward their solution. The time has passed when the publication of the limnetic species, or even the quantitative determination of the constituents of plankton can materially further the advance of science. This work was useful, chiefly in disclosing to us the problems of limnology. These are now before us, in part at least, and the time has come when the student of lakes must attempt to answer some of them.

E. A. BIRGE.
UNIVERSITY OF WISCONSIN.

---

*A PRELIMINARY ACCOUNT OF SOME OF THE RESULTS OF THE PLANKTON WORK OF THE ILLINOIS BIOLOGICAL STATION.**

THE Illinois River drains an area of 29,000 square miles, is over 500 miles in length, and has at low water a fall of but 31 feet in the last 227 miles of its course. The low gradient is due to the fact that, in a part of its course at least, the present stream and its bottom lands occupy the bed of an ancient outlet of Lake Michigan. The present flood plain is but partially developed—the bank height rarely exceeding 15 feet—and overflows are frequent and extensive. Floods rise from 16 to 24 feet above low water levels, increasing the total extent of water area to over 700 square miles. The impounding action of the bottom lands, the low gradient, and the backwater from the Mississippi River combine to prolong the flood period. The stream at low water is from 500 to 1500 feet in width and three to 12 feet in depth, and by reason of the dams forms a series of slackwater pools with a sluggish current of about one-half mile per hour. The waters of the adjacent lagoons, bayous, and lakes are also shoal and attain a high temperature during the period of summer heat. The water is rich in organic matter being derived from the run-off and seepage of fertile prairie soil and is further fertilized by the sewage of a metropolis and of a score of smaller cities along its banks, in addition to the offal of extensive cattle-yards and large amounts of distillery wastes. Under these conditions it is not surprising that ammonia, nitrites and nitrates are present in excessive quantities. The high temperature and the abundance of nutrition thus favor the development of the aquatic flora and in sequence that of the aquatic fauna.

Quantitative investigations of the plankton have been carried on at somewhat regular and frequent intervals from June, 1894, to April, 1899, in a series of representative localities near Havana, Ill.; (1) the main stream; (2) Spoon River, a typical tributary; (3) Quiver Lake, rich in vegetation much of the time and fed by spring water; (4) Thompson's Lake, a large (6 × .5 miles) open lake, fed by the river and usu-

* Abstract of address in opening discussion on Methods and Results of Limnological work at meeting of Naturalists at Chicago, December 28, 1899.

ally free from vegetation; (5) Phelps Lake, an ephemeral body of water without vegetation; (6) Flag Lake, a large swamp, choked with vegetation, rarely drying up in the summer. At times of high water all these localities are submerged. The quantitative and qualitative examination of the collections, as yet incomplete, indicate the following more or less tentative conclusions:

1. The waters contain a typical fresh-water plankton, that is, one composed of limnetic organisms usually cosmopolitan and identical with or closely related to the plankton organisms of larger bodies of water. It has much in common with the plankton of German streams, and at low water is remarkably like that of the Nile at a corresponding stage. The admixture of littoral forms in the open water of the lakes and in the river is surprisingly small in the number of individuals, though presenting a considerable range of species. In all about 500 different species have been found, of which at least one-third may be called limnetic.

2. There is a marked seasonal variation in the amount of the plankton. A spring maximum, usually in May or June, follows the winter minimum and is in turn followed by an apparent mid-summer minimum in August. An autumn maximum of secondary importance precedes the return to the winter minimum. These statements are based, as usual, upon catches made with the silk net and are subject to the error arising from the leakage of the smaller organisms through the silk. The correction of this error by supplementary methods tends to eliminate the summer minimum and to augment the autumn maximum. The volume of plankton in the spring maximum is from 20 to 50 times that of the winter minimum. These fluctuations are repeated from year to year, but vary in time of appearance, in extent, and in relative development in successive years and in different waters. Irregular fluctuations also of great extent may occur in any locality especially during the summer and fall.

3. There is a marked seasonal variation in the organisms composing the plankton. During the winter minimum the chlorophyll bearing forms are relatively few, the plankton being composed of a few hibernal and a smaller number of perennial species principally of Rhizopoda, Copepoda and Rotifera. The presence of ice on the surface, and the low temperature of the water (0°–4° C.) do not interfere with the growth and reproduction of this winter plankton. Fouling of the water by an excess of sewage under the ice may, however, exterminate the animal life of the water. As the temperature rises, the brown flagellates and the diatoms increase in number and subsequently the green flagellates and other chlorophyll-bearing organisms multiply rapidly. This is accompanied by a marked development of animal forms, especially Cladocera and Rotifera, resulting in the spring maximum. This culmination is rarely due to the excessive development of a single species, but is typically polytonic. A rapid decline of the vernal species, principally Entomostraca and diatoms, produces the midsummer minimum, characterized by the relatively small number of individuals, and the very large number of species, principally Rotifera and the smaller green flagellates. The autumn maximum appears after the equinoctial rains and is often composed in large part of Synchæta, Synura, and diatoms. This is also the period of maximum numbers of the ciliate Protozoa. The total number of species in the fall plankton is not large and the predominant forms are few.

No two years present throughout the same sequence of species in the same relative numbers. In some instances, species abundant in one year have not been found or have occurred but sparingly in other years. As a rule the numbers of individuals and their seasonal range are alike subject to considerable fluctuations from year to year. The qualitative differences in the plankton from season to season are due to the adaptations of different species to different seasonal conditions, especially in the matter of temperature, and the differences from year to year are perhaps to be correlated with the fluctuating environment.

4. At times of high water all plankton stations at which examinations have been made are in one continuous body of water, and the plankton is quite similar throughout, especially in spring floods. As the water recedes and the several lakes and the river emerge as distinct units of environment, the planktons are very quickly differentiated by the disappearence of certain species and the multiplication of others as seasonal changes progress, so that in a few weeks each locality presents its own peculiar assemblage of organisms. This phenomenon is repeated from year to year and occasionally several times in one year, depending on the fluctuations in the river levels. The different localities examined thus present at times of low water great local differences in the amount and constitution of the plankton, corresponding to contrasts in the environment, especially in respect to vegetation, source of water and temperature. The assemblages of organisms characteristic of a given locality, though varying somewhat, present many points of similarity from year to year.

5. Waters in which aquatic plants, such as *Ceratophyllum*, *Elodea*, *Naias*, *Potamogeton* and *Nymphœa* are abundant, are, in the localities examined, as a rule poor in plankton. The removal of the vegetation by wind and flood or by fishermen's seines is followed by an increase in the amount of plankton. The same lake may then be plankton-rich one year and plankton-poor the next, according to the amount of vegetation it contains. The phyto-plankton thus apparently replaces the coarser aquatic flora.

6. The local distribution of the plankton in lakes with somewhat uniform conditions of bottom, water supply, and vegetation is remarkably even, in so far as the volume of the plankton is concerned, the variation from the average falling within the 30 per cent. observed by Apstein in the lakes of northern Germany. The distribution of many species is far less uniform. In the river, except near the mouths of large tributaries the distribution of the plankton is even more uniform than it is in the lakes, the variation in the amount of the plankton from shore to shore is less than 10 per cent. Under even conditions the amount of plankton in the current of the river ($\frac{1}{2}$ to $2\frac{1}{2}$ miles per hour) varies but little from hour to hour and day to day—being often within 10 per cent. and rarely exceeding 20 per cent. at one point of observation at Havana. Catches made at intervals of 10 miles in the lower 220 miles of the river show a considerable uniformity in amount and constitution, except where modified by local conditions such as sewage on tributary waters.

7. The plankton of tributary streams is relatively very small in amount and is composed of a different assemblage of organisms. The immediate effect of tributary waters is to dilute the plankton. The river is thus a unit of environment with its own peculiar fauna and flora.

8. Flood waters quickly and profoundly affect both the amount and the composition of the plankton, diluting it and washing it rapidly away toward the sea and to a slight extent replacing it with the more or less sessile forms torn away by the current of the creeks and of the river itself. The silt of flood waters is often disastrous to many species of Entomostraca. The recovery in the volume of the plankton after floods is

usually rapid, the chlorophyll bearing organisms, especially the green flagellates appearing first, followed in turn by the animal plankton, Protozoa, Rotifera and Entomostraca. The resubmergence of the bottom lands doubtless starts anew encysted forms left by receding waters. In general the recovery from the flood culminates in a plankton maximum of greater or less importance, depending upon the season of the year and the extent of the flood.

9. Species present in great numbers are often extremely variable, as for example, *Brachionus bakeri*. The varieties are often local, or seasonal, but may also be coëxistent. Variation is often very great in the case of species reproducing parthenogenetically as the rotifer just mentioned, in other rotifers, in Daphnia and in Bosmina.

C. A. Kofoid.

MALARIA AND TUBERCULOSIS.*

The visit of certain English physicians to Italy during the Christmas vacation, was in some respects so remarkable as to make a full description of it of general interest. Commendatore Florio, a wealthy and beneficent citizen of Palermo, invited certain English physicians first to Rome, in order to see the work done by their Roman brethren in the investigation of malaria; and, secondly, to Palermo, to inspect a sanatorium for the cure of consumption which Commendatore Florio has erected under the advice of Professor Cervello, of the University of Palermo. The party of English physicians with their friends was about twenty in number, among them being Sir T. Lauder Brunton, Sir Walter Foster, M.P., Professor Clifford Allbutt, of Cambridge, Dr. Manson, C. M. G., and Dr. Cantlie, of the London Tropical School. Dr. Malcolm Morris and Dr. St. Clair Thompson represented the National Association for the Prevention of Tuberculosis, and Dr. Gibson represented Edinburgh. They were received at Charing-cross Station by Commendatore Florio's representative and travelled with him to Rome, where they remained for some days in conference with Professors Grassi, Bignami, Celli, and Bastianelli. Signor Grassi, now Professor of Zoology in the University of Rome, is a Sicilian, and while a professor at Catania carried out the remarkable researches on the propagation of the eel which secured for him the Darwin Medal of the Royal Society.

Professor Grassi, since his removal to Rome, has performed work perhaps no less remarkable in demonstrating the propagation of malaria. This story is not only so interesting in itself, but of such vital importance to our own colonies, some of which are desolated by malaria, that I will try to sketch briefly what will be told in full by Professor Grassi in an illustrated volume to appear very soon both in Italian and English. A few years ago M. Laveran won a place for himself on the distinguished roll of Frenchmen of science by discovering in the blood of malarious patients a minute parasite, a form belonging to the humblest order of animal life. Three different but closely allied species of parasite are severally concerned in the causation of the three kinds of malarial fever. M. Laveran's researches were fully verified by observations both in Europe and in America, and further observations made of their behavior in man. Certain suggestive facts led Dr. Manson to suspect that a gnat or gnats were the means of propagating the parasite, and, having himself returned from the tropics, he pressed Major Ross, then of the Indian Medical Service, to follow up this clue in India. Himself an ardent engineer and now chief of the Liverpool Tropical School, Major Ross set to work with some success, but unfortunately his efforts were impeded by

* From the London *Times*.

the active discouragement of his official superiors in India. Thus hampered he was able, nevertheless, to ascertain that a gnat (a culex) is the means of propagating a malaria in birds but not, as it turns out, any one of the malarial parasites of man. At this point the Roman physicians took up the subject, Professor Grassi on the side of zoology, Professor Bignami of pathology, Professor Celli of prevention. Their researches have proved, and Major Ross has since verified their statements in West Africa, that malaria in man also is propagated by a gnat, but not by a culex; the enemy of man is a dapple-winged gnat, scientifically known as *Anopheles claviger*. Professor Grassi showed to his visitors a large number of beautiful drawings illustrative of the anatomy of this gnat, and of the life of the parasite within it. The gnat, in sucking the blood of an infected man, takes in the parasite; this in a spheroidal form may be demonstrated in the stomach of this fly, and its course, followed closely as it penetrates the walls of the stomach, reaches the juices of the body, as a tiny worm-like creature, and thus wriggles onwards into the salivary (or poison) gland of the insect, whence it is again returned to man by the proboscis. Thus between man and the anopheles these parasites maintain their cycle of life. No man, and no dapple-winged gnat, no malaria.

Not the least interesting part of the visit was the excursion with the professors into the Campagna, where two farms had been selected for experiment. In the one protection was given against the access of the insects; in the other no such precautions were taken. Other things were equal; in the former farm was no malaria, in the latter malaria prevailed as before. Fortunately *anopheles* rarely bites men on the move; secreting itself in their cabins or chambers it attacks them while at rest—especially at night, when by certain apparatus its inoculations may be avoided. Whether *anopheles* can be extirpated or not is a large and difficult question. This gnat breeds in pools of a certain kind, not quite stagnant, but supporting confervæ (Limna), on which its larvæ subsist. From such pools these larvæ were collected and exhibited in abundance to the visitors. A small spoonful of common petroleum oil will destroy all the larvæ in a square yard of such water, and it seems possible, therefore, that by drainage, where possible, and the supplementary use of oil the insect might be removed from large areas. In turning up new ground such pools are apt to form and breed the gnat, a result which might be avoided by no very difficult provision. By his generous invitation Commendatore Florio has enabled skilled English observers to verify these invaluable researches—researches into the minute habits of very obscure creatures which will have nevertheless a very large effect upon the well-being of man in fertile tracts of the world now too pestiferous for continuous occupation, at any rate, by white men.

The cure and prevention of tuberculosis has of late years excited the public interest more than of malaria, of which fell disease our home population now happily knows little. From Rome Commendatore Florio's guests were taken to Palermo, and were entertained in the Villa Igiea, the exquisite palace, for I can call it no less, in which consumptive patients are to be received and treated on the open air system, with all advantages that a beautiful and uniform climate, a lovely site, and every luxury of life can give. The sanatorium, which will be completed in a few months and then opened by the King and Queen of Italy, is built outside Palermo upon the rocks on which the deep sea of the bay actually beats. In the clefts of these sunny rocks are marble benches, temples and grottoes, and about their sinuous margins winds terrace upon terrace broadening up to the plateau on which, some forty yards from the sea, the sanatorium stands, sheltered behind to the north by the mass of Monte Pellegrino. Of this great and splendid curehouse, Professor Cervello is the physician in chief, and Baron Fassini, whose charming qualities as a host endear him to his guests, is the director. The most perfect modern systems of cure have been studied in Germany and elsewhere by Professor Cervello, whose dietetic regulations will be rendered less oppressive by the ministrations of a first-rate French chef, and whose draughts of fresh air will be administered to those who desire it in a beautiful yacht of 300 tons, which is always to be at the call of the patient. In Palermo Commendatore Florio himself, the Messrs. Whittaker and other residents did their utmost by brilliant hospitality and constant kindness to make the visit of the English physicians and their friends a memorable one; and not the least delightful of their memories will be that of the sanatorium and its grounds illuminated by myriads of lamps and hundreds of men with torches as they steamed away from the harbor on the night of their departure.

It is urged on behalf of the Villa Igiea that Palermo is the nearest place to the Continent of Europe where so delightful a climate is to be had, where there are so many resources for quiet cheerfulness and so much charm for the eye and imagination. But it is needless to add that residence in a fairy place, with a French cook and a yacht at command, can be no cheap cure. The sanatorium when finished will accommodate about 100 patients, who must necessarily belong to the wealthiest class of society.

In respect of finance I must add that Commendatore Florio did not issue his generous invitation with any eye to commercial advertisement. He has built the Villa Igiea with no intention of personal profit; after providing a fund for repairs and contingencies, all surplus is to be set aside for building a sanatorium or sanatoriums for the poor. He was also wishful that English physicians should see at work a method of inhalation of the vapor of formaldehyd which Professor Cervello believes will prove a very valuable ally in his treatment of pulmonary phthisis. This method the Professor has used for some time in the consumption wards of his hospital with, as it appears to him, satisfactory results. Whether this method turns out to be valuable or not, and this time only can show, there can be no doubt even now that the Villa Igiea offers incomparable advantages as a sanatorium for the modern system of cure of the most grevious of all pests of man.

SCIENTIFIC BOOKS.

Social Laws. An Outline of Sociology. By G. Tarde. Translated from the French by Howard C. Warren, Assistant Professor of Experimental Psychology in Princeton University, with a preface by James Mark Baldwin. New York, The Macmillan Company. 1899. Small 8°. Pp. xii + 213.

This little book consists of a collection of lectures delivered by M. Tarde at the *Collège Libre des Sciences Sociales* in Paris during the month of October, 1897. The French edition appeared in 1898 under the title, *Les Lois Sociales; Esquisse d'une Sociologie.* It has now come forth very opportunely in an English dress, which enables those who do not keep a close watch for important contemporary foreign literature to acquaint themselves with the views of one of the leading thinkers of our time. It does not claim, as the author is at pains to say, to give a summary of his three principal works, The Laws of Imitation, Universal Opposition, and Social Logic, but rather to show what there is in common in these works, and how they together constitute a system of social philosophy.

There is one respect in which Tarde may be compared with Malthus. Each, in studying man and society, arrived at a biologic law applicable to both man and the organic world below man. There is, however, this difference, that while Malthus discovered a law of biology that had not as yet been recognized by biologists, Tarde has discovered a law well known to biologists, but scarcely as yet recognized as a law of sociology. Another difference is that the Malthusian law, while it holds universally in the animal world and is true of man as an animal, is not true of rational man, having been superseded by the law of mind, which has inaugurated a new dispensation; whereas the Tardean law, if we may so speak of it, is as true of the rational man as of the animal man and the animal, and, broadly interpreted, takes in the inorganic as well as the organic world. This Tarde has perceived, and he expresses it in this book in the following words: "The time has come when it would be in place to set forth the general laws governing imitative repetition, which are to sociology what the laws of habit and heredity are to biology, the laws of gravitation to astronomy, and the laws of vibration to physics" (p. 61). Nor is this the first time that he has said such things. Sweeping comparisons of the kind are frequent in the works named. We may refer especially to the footnote on page 37 and the discussion on page 159 of the second edition of the *Lois de l'Imitation*.

What, then, is this Tardean law? Most readers have become familiar with the five leading terms of Tarde's philosophy: Imitation, Repetition, Opposition, Invention, and Adaptation. The one most dwelt upon is *imitation*. Next to this *invention* has come to be recognized as having been given a special meaning by Tarde. We read less about *repetition* and *opposition* in their new rôles, while *adaptation* scarcely receives any amplification at Tarde's hands.

First, then, as to *imitation* as a social law. That men have always imitated one another, especially in what they deemed good, is, of course, well known, but it had not been perceived that this is the basis of all custom, of all morals, and of the social order. Imitation is specially characteristic of the lower races and of the higher animals. The first of these facts is a common remark of travelers and ethnographers. The second is attested by language itself, the word for *ape* in most languages being that for mimicry. In the development of mind imitation is the natural and necessary precursor of imagination, and all early art consists in mere copying. Who has not noted the slavish conventionalism of aboriginal and even civilized art patterns? Below the psychic plane and in the simple world of life, the homologue of imitation is clearly *heredity*, *i. e.*, reproduction of what already exists. But this is only transmission from one body to another. The same process is going on within the organic body. Here it takes the name of *nutrition*, and growth itself is a form of imitation. Below the life plane and throughout the inorganic world something very similar takes place. Here it is simply *impact*, producing motion, and the physical homologue of imitation is *causation*. Imitation is the universal conservative principle of nature.

Repetition is included in imitation. It is the mechanical effect of which imitation is the physical cause. It results whether the force behind it be psychic, vital, or physical. It is therefore rather an accessory term expressing the necessary consequence of imitation than a new coördinate fact in Tarde's system.

Opposition is the resistance with which the effort to repeat, reproduce, and perpetuate constantly meets from the impinging environment. It is, as Tarde says, 'universal.' In human society it embraces not only the conflicts with the elements and with wild beasts, but the far more formidable conflicts among races and nations—*bellum omnium contra omnes.* It is also oppression and revolution, monopoly and competition, and the strife of capital and labor. In the organic world it is nothing short of the universal 'struggle for existence,' so clearly set forth by Darwin. In a word, it represents the environment. In the physical world it is the innumerable obstructions in the path of every moving body, producing collisions and arresting, deflecting, constraining, and transmuting motion.

Invention is the first step in advance. It is not universal, but appears sporadically. It is well described by Tarde in the following passage: "Social transformations are explained by the appearance, to a certain extent accidental as regards time and place, of certain great ideas, or rather by a considerable number of ideas, small or great, easy or difficult, usually unperceived at their origin, rarely brilliant, generally anonymous, but ideas always new, and which, by reason of this newness, I will allow myself to baptize collectively as *inventions* or *discoveries*" (Lois de l' Imitation, p. 2).

Invention breaks away from the bonds of imitation. Instead of exact repetition and reproduction of the old pattern it adds something, however little, to it, and this in the direction of improvement. This is a permanent gain, because the improved state immediately becomes in turn the subject of imitation. The word invention is given the greatest possible latitude. It embraces everything that departs in the least from the strict line of exact reproduction and perpetuation of the existing type. A thousand causes lead to it. Tarde has not worked these out as well as he might. Necessity may have been the primordial mother of invention as a condition to further existence. But with the growth of mind a certain degree of nonconformism naturally arose. The obstacles to the satisfaction of desire (opposition) bred discontent and induced efforts to overcome them. Mind is the naturally aberrant element in the world, and deviations from the straight path of custom resulted. At long intervals, few and far between, even as now, the inventors, *i. e.*, the innovators, made their appearance, with the results described by Tarde.

What, now, is the relation of invention to imitation and opposition? It is the product of the joint action of both of these. We saw that imitation and repetition constitute causation in the domain of thought and ideas, also in that of life. They are the *force* at work in these fields. They are the *causa efficiens*, the *vis a tergo*, that propels the vital and psychic worlds. As such they obey the Newtonian law, and the motion resulting is in straight lines. Cause and effect are in intimate contact, and this repetition, or rectilinear motion is simply continuance, *i. e.*, *continuity*. But opposition interferes with this, tends to arrest motion, constrains and transmutes it. So far the process is *genetic*. But mind is *telic*. It is a *final cause*. It was developed as a means of overcoming opposition, of surmounting obstacles, of avoiding resistance, and of circumventing counter-forces, in order to attain foreseen ends. This is the essence of invention, which is therefore born of the repetitive *nisus* in conflict with the obstructive environment, *i. e.*, of imitation and opposition.

As invention seems to be wholly the product of the higher mind and late in origin, it might be supposed that, unlike imitation, repetition and opposition, it would have no homologue in the animal world or on the plane of mere vital existence, and still less in the field of purely physical phenomena. Not so, however. Just as in the organic world, heredity is the homologue of imitation, and environment is the homologue of opposition, so *variation*, the product of heredity and environment, is the homologue of invention, the product of imitation and opposition. Dropping now into the physical world, where, as we saw, causation is the homologue of imitation, and collision is the homologue of opposition, we see that the product of these is *evolution*, which is therefore the true cosmic homologue of invention.

Adaptation, as the final great social law, is perhaps more fully treated in this little book than in any of Tarde's previous volumes. He devotes the third and last chapter to it, occupying 58 pages of the English text. And yet this is the least satisfactory part of Tarde's system thus far. This is not because it is not equally important, but because it is not set forth with anything like the originality and power that characterize his treatment of the other great laws. This is perhaps partly because he found the field thoroughly worked over by the biologists, and there is so little new in sociological adaptation. But he says justly that adaptation "expresses the profoundest aspect under which science views the universe." He perceives that it is a progressive coördination of social phenomena, and in a sense a synthesis of repetition and opposition, just as in biology it is a development as the result of a synthesis of heredity and environmental resistance. But he does not work out the mode of operation of this law in a way analogous to that in which Darwin worked it out in biology, nor does he give us the sociological equivalent of natural selection, philosophically expressed by Herbert Spencer in the phrase 'indirect equilibration.' Adaptation is an indirect social equilibration, the complete analysis of which remains to be made. Tarde, indeed, dwells on the fact that adaptation consists in a certain harmony and unity in the social world, from which it is clear that he sees the dependence upon it of the social order. Between adaptation and invention, in Tarde's wide use of both terms, we have an antithesis which in its essential aspects is the same as the antithesis between order and progress. It is just here that sociology naturally falls into the two great subdivisions of social statics and social dynamics.

It may be objected to the above analysis that it does not follow closely enough the method of the work under review, and that it goes back to the author's other works and even lays the conceptions of other authors under tribute. But this could scarcely be avoided in anything beyond pure exposition. As a matter of fact very little is said in this book of the great law of invention. But how could this be avoided in any glance at his system? The aim has been rather to summarize that system and present it as a whole, while laying special stress, as Tarde claims to do in this work, on the relations that the leading laws sustain to one another. But the system is a large one. It is thoroughly elaborated in a long series of books, and different readers may see many things very differently. Again, the excessive condensation necessary to a short review compels the omission of so many important things that no claim is made to having done justice to that system.

The English text forms a neat and convenient little volume, printed in clear type and tastefully brought out. The translation is free and the original is rendered in elegant English without obscurities or gallicisms. In a few cases it is open to the charge of being just a little too 'liberal.' Only one such need be referred to. On page 168 the original: "Et ce cas tend à se généraliser par les progrès de la machinofacture," is rendered by: "And this sort of case tends to become more general with the improvements in the manufacture of machinery." Aside from the fact that this does not convey the idea of the original, there is certainly a loss in avoiding the word *machinofacture*. This is a word of Tarde's special mintage, struck off with all due reserve in a footnote to page 174 of the *Logique Sociale*, and freely used thereafter, often as here, without italicizing, on the assumption that his readers now understand it. But it is as good English as French, and while in both languages the word *manufacture* has lost its literal implication of *handmade*, and embraces machine-made products as well and for the most part, still it was a fine stroke to call attention by this new term to the primitive form of industry, and to emphasize in one word the enormous stride that industry has taken, which, with all its blessings, is at the same time the fundamental cause of the chief socio-economic problem of modern times.

LESTER F. WARD.

Die Conchylien der patagonischen Formation. Von H. VON IHERING. Mit 2 Tafeln. *Neuen Jahrbuch für Mineralogie, Geologie und Palæontologie.* Jahrg. 1899. Bd. II. (S. 1–46 Taf. I., II.).

In this paper Dr. von Ihering has made an important addition to the invertebrate paleontology of the Patagonian beds. The paper is based upon a collection of invertebrate fossils recently made by Mr. C. Bicego of the Sao Paulo Museum, from the typical Patagonian beds at the mouth of the Santa Cruz river in southern Patagonia. According to Dr. von Ihering about 50 species are represented in the collection. Among these are nine new to science and some three or four new varieties.

Not the least important features of Dr. von Ihering's paper are the geological questions discussed in it. Following Dr. Ameghino, von Ihering considers the Patagonian and Supra Patagonian (Santa Cruz) beds, as quite distinct and proceeds to set forth at some length the paleontologic and lithologic features which according to him are characteristic of each. Happily we have here for the first time a definite locality given where the Patagonian beds may be observed in their typical development and exhibiting those lithologic and paleontologic features, which, according to Dr. von Ihering, distinguish them from the Supra Patagonian beds. This alone is a most important point, since it gives us a definite base from which to start in a comparative study of the Tertiary formations of Patagonia, as they are understood by Drs. von Ihering and Ameghino. It is to be hoped that the latter author will also, in the no distant future, realize the importance of giving at least some one definite locality at which each of the various geological horizons (Mesozoic and Tertiary) that have been named by him at various times may be found and studied. It is alone by such frankness, which should characterize the work of naturalists everywhere, that we shall be able the more easily to arrive at a true solution of the age and relations of the various geological formations of Patagonia.

According to Dr. von Ihering (see page 4 of his paper), the fossil shells of the Santa Cruz (Supra Patagonian) beds are usually enclosed in a soft, sandy matrix, while those of the Patagonian beds are firmly imbedded in very hard clay stones. Dr. von Ihering does not contend that these conditions are absolute throughout the two series, but that the former prevails in the upper series while the latter predominates in the lower. He also finds the faunas of the two deposits to be quite distinct. On pages 6 and 7 he gives a list of 67 species as belonging to the Patagonian beds. He finds only 16 of these 67 species in the Santa Cruz (Supra Patagonian) beds. On page 38 he gives a number of genera and species which according to him are characteristic of the Santa Cruz (Supra Patagonian) beds.

Regarding the lithologic characters given by Dr. von Ihering, it should of course be remembered that he has himself never visited Patagonia, and has therefore to rely upon the nature of the matrix adhering to the fossils and the reports of Mr. Bicego, whose observations in southern Patagonia have been limited to the region about the mouth of the Santa Cruz river. But even in that locality Mr. Bicego certainly could not have failed to observe that the lithological conditions given by Dr. von Ihering, as prevailing in the Patagonian beds, are in reality, of extremely limited extent when compared with the entire thickness of fossil-bearing rocks at this locality. There are, as Dr. von Ihering says, many instances of hard clay-stones or other concretions literally filled with the shells of mollusca, and occasionally a stratum of hard sandstone, which is also fossilliferous. The superior resistance which such materials offer to erosion are apt to mislead the not too careful collector as to their relative importance, and with such material at hand, and to be had only for the picking up, he is likely to overlook many of the real gems which will richly reward the collector if he turns to the several hundred feet of soft sand and clays and examines them *in situ*. On weathering away, however, the usually soft delicate shells are reduced to powder and rendered worthless. If Mr. Bicego had occasion to examine the bluffs along the south side of the Santa Cruz river, between the village of Santa Cruz and Direction hill at the mouth of the river, he must have seen numerous shell layers in the soft crumbling sands and clays, which constitute by far the greater portion of the 350 feet of sediment exposed in the bluffs. A notable example of this is to be seen in the bluff of the river about one and a-half miles above Direction hill and just above where formerly stood the temporary observatory erected a few years ago by the United States Steamer *Brooklyn* (?). At this point the bluffs rise directly from the river and there is a continuous stratum of loose sand, filled with shells. This stratum is about six inches thick and a quarter of a mile in length. It is located at a height of only five to ten feet above high water and can scarcely fail to attract the attention of anyone passing along the foot of the cliff. At various altitudes above it, other similar shell-bearing layers may be seen in the same bluff. At Direction hill and along the coast to the southward are many other strata of soft materials rich in fossils, while if any one will take the trouble at low tide to walk out over the surface of the beach he will frequently see the soft tosca literally filled with fossil shells. In one soft stratum near the mouth of the river the writer found a bed about eight inches thick and 20 to 30 feet in length, composed almost entirely of the shells of *Struthiolaria ornata*, which according to von Ihering is characteristic of the Patagonian beds, mingled with a few specimens of *S. Ameghinoi*, which, according to the same author, is found only in the Supra Patagonian (Santa Cruz) beds. Moreover, there are a number of blocks of the hard matrix from the mouth of the Santa Cruz river and now in our collections in the museum, mingled together in the same block are to be seen various species, some of which, according to von Ihering, are characteristic of the Patagonian and others of the Supra Patagonian (Santa Cruz) beds.

Dr. Ortman, who is making a thorough study of our collections of Tertiary invertebrates from Patagonia, is entirely unable, from the list of species given by Dr. von Ihering (page 38), as characteristic of the Patagonian and Supra Patagonian (Santa Cruz) beds, to refer any of the numerous horizons from which our collections have been made to either the one or the other series of beds, on account of the mingling of these alleged characteristic species. He finds represented in our collections from the typical Patagonian beds at the mouth of the Santa Cruz river all but one of the genera and species given by von Ihering (p. 38) as characteristic of the Supra Patagonian (Santa Cruz) beds. This one exception (*Voluta ameghinoi*) he finds in our collections from the Mt. of Observation associated with *Cardium puelchum*, *Cardita patagonica* = *inæqualis*, *Siphonalia noachina*, which according to von Ihering are characteristic of the Patagonian beds.

Of the sixty odd species given by von Ihering (pp. 6–7) as coming from the Patagonian beds, Dr. Ortman is able to at once designate thirty-five of them as occurring in our collections associated with one or more of the characteristic species of the Supra Patagonian (Santa Cruz) beds as enumerated by von Ihering (p. 38), while every single one of the latter species has been found with von Ihering's characteristic Patagonian species. It will thus be seen that it is clearly impossible to distinguish these two formations by their faunas, while the lithologic characters are even less distinctive. Nevertheless there are in certain instances decided lithologic and faunal differences at the various localities, and it sometimes happens that such differences are quite marked even in the same actual horizon and at neighboring localities. To such local differences due to the varying conditions attending the deposition of the beds, is due the confusion regarding their stratigraphic relations. Before making more extended observations, the present author like Drs. von Ihering and Ameghino, was in favor of considering these beds as composed of two distinct formations. Subsequent observations, made at many different localities, have convinced me, however, that the Patagonian and Supra Patagonian beds do not represent distinct time intervals, but that sedimentation was continuous from the base to the top of the series, and that the strata of which they are composed all belong to one formation (the Patagonian formation). The rocks composing these beds were laid down, as the fossils clearly indicate, either in a shallow sea or as littoral deposits. The shallow sea deposits constitute the Patagonian phase of the series, while in the Supra Patagonian phase are included the sands and muds that were accumulating simultaneously along the shores and smaller estuaries as their included fossils clearly indicate. The Patagonian phase prevails at the base and the Supra Patagonian at the top of the series, but neither is restricted to any definite horizon within the limits of the entire series.

On page 29, Dr. von Ihering enters upon a discussion of the age and relative position of the various sedimentary formations of Patagonia, giving a review of the conflicting opinions expressed at different times by various authors on these questions. He also points out the erroneous ideas formerly held by Dr. Ameghino regarding the relative, stratigraphic position of the *Patagonian*, *Supra Patagonian and Santa Cruz beds*. In this general *résumé* he has fallen into an error regarding the position taken by myself in a former paper with reference to the stratigraphic position and age of the *Pyrotherium beds* of Ameghino. Since others, more especially Drs. Ameghino and Roth, have also misunderstood the position taken by me at that time on this question I shall improve the present opportunity to explain a little more fully my views concerning the Pyrotherium beds. I did not, as these authors seem to think, place the Pyrotherium beds above the Santa Cruz beds. I placed them in the Cretaceous, where according to Ameghino they belonged.

I did, however, seriously question both their Cretaceous age and the stratigraphic position assigned to them by the Ameghinos. From a study of Dr. Ameghino's description of the mammalian fauna found in them, I advanced the opinion that there were mingled together in the so-called Pyrotherium fauna, representatives from two or more distinct horizons. This opinion Dr. Ameghino has since admitted to be a fact and has separated his Pyrotherium beds into two distinct formations which he separates by a long time interval. My succeeding two years of field-work in Patagonia have further convinced me as to the correctness of my former views regarding the *Pyrotherium beds.*

In referring on page 30 to the paleontologic evidences advanced by myself regarding the age of the Pyrotherium beds, Dr. von Ihering is quite right in saying that the tooth mentioned and figured by myself as belonging doubtfully to Pyrotherium, is a tooth of Astrapotherium, and also in maintaining that in the process of development of any mammalian phylum, certain organs may early attain a considerable degree of specialization, while the animal as a whole remains quite primitive in its structure. Everyone I presume will readily grant this, but would Dr. von Ihering have us entirely overlook the extremely close relationships, brought out on almost every page of Dr. Ameghino's papers on the Pyrotherium fauna, as existing between the so-called Cretaceous fauna of the Pyrotherium beds and that of the Santa Cruz beds, which latter are now known to be not older than Miocene? Many of the mammals described by Ameghino from the Pyrotherium beds are scarcely specifically distinguishable from allied forms in the Santa Cruz beds. In a few instances Ameghino has himself admitted that he can not distinguish forms from the Pyrotherium beds from well-known Pliocene and Pleistocene animals. Among such may be noticed the large gravigrade edentate which he is unable to distinguish from Mylodon, more than likely for the very good reason that it is a tooth of Mylodon from thePleistocene deposits that occur throughout the greater part of Patagonia.

Considering the highly specialized character of the Pyrotherium fauna and its remarkably close relationship as a whole to the Santa Cruz fauna, in connection with what we already know of the character of the stratigraphic work of the Ameghinos in Patagonia, the Cretaceous age of the Pyrotherium beds can no longer be seriously considered. Moreover the stratigraphic observations of Dr. Roth, Señor Mercerat and myself are all at variance with such a position for them.

On page 45 Dr. Von Ihering includes the Cape Fairweather beds in the Tehuelche formation as is also done by Ameghino. If I mistake not the term Tehuelche formation was proposed by Doering for the great bowlder or shingle formation of Patagonia. Unfortunately I have never been able to see Doering's paper. If I am correct in this the Cape Fairweather beds should not be included in the Tehuelche formation since they are quite distinct and unconformable as I have been able to observe at several different localities. The Cape Fairweather beds are Pliocene while the Bowlder formation is unquestionably Pleistocene. A curious account of the relations of these two deposits has been published by Dr. Ameghino in the *Geological Magazine*, for January, 1897. On page 17 in speaking of these two series of beds he says, after quoting at some length from a letter from his brother, Charles Ameghino: "According to this the bowlders were deposited at the bottom of the sea and over them there extended at other periods a vast formation of marine shells." In this instance Dr. Ameghino has again reversed the true stratigraphic relations as he did for many years with the Patagonian, Supra Patagonian and Santa Cruz beds.

J. B. Hatcher.

Geological Survey of Canada. By George Mercer Dawson, C.M.G., F.R.S., etc., Director. Annual Report. (New Series.) Vol. X. Ottawa, December, 1899.

This volume, comprising 1046 pages of text accompanied by eight maps and illustrated by twelve plates and a number of figures in the text, has just been issued by the Department and forms publication No. 679 of the Catalogue of volumes published by the Canadian Survey. It is addressed to the Hon. Clifford Sifton, M.P., Minister of the Interior, and contains many valuable reports of exploratory and geological surveys, both in the little known districts of Canada, as well as in the densely populated and older provinces of the Dominion of Canada. The volume opens with a 'Summary Report of the Operations of the Geological Survey for 1897,' by the Director.

This report describes the various publications issued during the year, the geological information on the Yukon District, Museum and office work, and also the result of boring operations in Northern Alberta. The Director also gives reports of explorations and surveys in British Columbia, Manitoba, Ontario, Quebec, Hudson Strait, New Brunswick and Nova Scotia. It is followed by Mr. W. McInnes's report 'On the Geology of the Area covered by the Seine River and Lake Shebandowan Map-Sheets,' in the gold-bearing series of Northern Ontario. The Laurentian, Couchich and Keewatin Steep Rock series, and Animikie series of rock formations occurring in that district are described and their contacts carefully noted. The localities which are productive and of economic value receive special attention and notes on the glacial geology are also included. This forms Report II. of the volume.

'Report on the Area included by the Nipissing and Temiscaming Map-Sheets,' by Mr. A. E. Barlow, forms Report I. of this volume, and comprises 302 pages of text, including two appendixes: (1) 'List of Elevations'; (2) 'On some Cambro-Silurian and Silurian Fossils from the Lake Temiscaming, Lake Nipissing and Mattawa Outliers,' by Henry M. Ami, of the paleontological staff. Mr. Barlow's report forms a very complete study of an important area of archæan rocks, in which he has described the main geological features with a great deal of pains, and gone into details of the composition of the gneisses met in the *Laurentian* of the area in question, together with their petrographical relations; also in the 'Grenville series' as developed and recognized by him in that district.

The *Huronian* system is then discussed, and the breccia-conglomerates, the diabase and gabbro and granites met with carefully described, along with their relations to the post-Archæan eruptives. He then devotes the succeeding chapters to a description of the Cambro-Silurian, Silurian and Pleistocene areas included within the two maps of the district examined, and has a chapter on 'Economic Geology' describing the valuable deposits of gold, silver, nickel, copper, iron and other minerals occurring there. Regional descriptions follow, which will prove of great value to prospectors and miners in a district, full of beautiful lakes and waterfalls and magnificent scenery, and holding economic minerals of untold wealth.

Report J, by Mr. R. Chalmers, 'On the Surface Geology and Auriferous Deposits of South-eastern Quebec,' contains upwards of 160 pages of very valuable reading and illustrations, with statistics of the gold production of the Beauce and Chaudière River region of Quebec. The pleistocene marine shore-lines, the rivers and lakes, the denudation that has taken place, together with the action and products of the Appalachian glacier, the Laurentide ice, and that of the local glaciers, as well as of floating ice, are all discussed. The gold-bearing region is then described. This includes the history of mining in the Gilbert River, River du Loup, Famine River, Mill River, Slate Creek, Main Chaudière Valley, Little Ditton River, etc. The probable source of the alluvial gold is then given by the author.

'The Mineral Resources of New Brunswick,' by Professor L. W. Bailey, forms Report M of this volume and is a most welcome report. This province ought to receive as well as give more attention to the materials of economic value, which occur in the earth's crust as it is developed in that portion of the Dominion of Canada by the sea. The geological formations, in which iron, copper, nickel, antimony, lead, silver, manganese, coal, bituminous shales, graphite, peat, gypsum, granites, marbles, dolomites, ornamental stones, infusorial earths, mineral springs, and various other materials of economic value to man are to be found, are described, and the mode of occurrence of these useful materials given, together with their locations. A map of the minerals of the province accompanies the report.

Report S contains the customary and useful report of the 'Section of Mineral Statistics and Mines,' by Mr. E. D. Ingall. It contains upwards of 200 pages of valuable notes on all the economic minerals of Canada from all the provinces, and tables of their value and of the amount produced and exported or consumed at home.

The volume contains a very complete index, which adds greatly to its value.

H. M. AMI.

North American Slime Moulds. By T. H. MACBRIDE. New York, Macmillan & Co.

The appearance of this book must be gratifying to all American students of the slime moulds. It is gratifying also that it comes from the pen of one who has long been identified as an ardent student of these lowly organisms, and whose former contributions to the literature of the subject have shown signs of a conscientious student. It follows closely after the appearance of two monographs covering the species of a much wider geographical area and including the American forms; the one by Mr. George Massee of the Kew Herbarium, London, Eng., and the other by Mr. Arthur Lister, of the British Museum, London, Eng. Nevertheless, it will be found convenient for American students because it is limited to American species, and especially because the author has had an opportunity of comparing a larger number of specimens representing the American species, than perhaps were accessible to the monographers mentioned above.

Each of these three authors arrives at a different conclusion after the usual course of reasoning in the selection of the name for the entire group. Massee uses the name *Myxogastres* first applied by Fries in 1829. Lister employs the name *Mycetozoa*, given by de Bary, in 1858, which included the *Acrasieæ* of recent discovery and the *Myxogastres* of Fries. MacBride choses the name *Myxomycetes*, substituted by Link in 1831 for Fries *Myxogastres*, but emended by deBary to include the exosporous species, the endosporous species only having been treated of by Fries and Link. The *Myxomycetes* of deBary thus formed a subdivision of his *Mycetozoa*. The author then says (p. 13), "Myxomycetes (Link) de Bary must remain the undisputed title for all true slime moulds, endosporous and exosporous alike."

In the introduction the author briefly describes the habits and morphology of the organisms. It is evident from his discussion on page 9 et. seq., that he considers them to be plants. But he very sensibly recognizes the difficulties here presented by a group of organisms, whose vegetable characteristics on the one hand ally them to the amœboid animals, and on the other hand give rise to no higher group. He says "it is purely a matter of indifference whether we say plant or animal, for at the only point where there is connection there is no distinction." There are given directions for the collection and care of material, and also is given a good bibliography.

In the taxonomic part of the book, the *Myxomycetes* (Link) de Bary are regarded as a class which is divided into three sub-classes. The first sub-class is the *Phytomyxineae* Schroeter, with one species, *Plasmodiophora brassicæ* which produces the common club foot of cabbage, turnips and other cruciferous plants. The second sub-class, the *Exosporeæ* Rostafinsk, includes two species, the well known *Ceratiomyxa fruticulosa* (*Ceratium hydnoides*) and *C. porioides*, which may be only a variety, or form, of the first named, as suggested from material collected by the writer at Ithaca, and indeed Lister considers it a variety only (Mycetozoa, p. 26). The third sub-class the *Myxogastres* (Fries) MacBride, represents the *Myxomycetes* properly speaking, and it is here that the large number of genera and species are to be found. 'Keys' are given first to the orders of which five are recognized. Then under each order are given keys to the genera and species, with synonymy and diagnoses, which latter are further made lucid by copious notes in most cases. The distribution of each species as at present known to the author is also given.

In his treatment of the nomenclature the author has not been led into many very painful upheavals of antiquated names, though in several cases the species appear under unfamiliar names, the most notable being *Mucilago spongiosa* for *Spumaria alba*. Forty-four genera are treated and over two hundred species. These are illustrated by eighteen excellent plates. The work is published in the attractive way so characteristic of many of Macmillan's books.

SECTION OF BIOLOGY.

THE regular meeting was held on January 8, 1900, Professor F. S. Lee presiding.

Mr. David Griffiths spoke of the structure of certain species of the *Sordariaceæ* and briefly reviewed the work which has been done on the group. Certain species were taken as types of the principal genera, and their life history traced, *Sordaria finicola*, *Podospora coprophila*, *Hypocopra equorum* and *Sporormia intermedia* being spoken of especially. Some time was devoted to a discussion of the much mooted question of fertilization in this and kindred groups. The principal methods of spore distribution were outlined.

Dr. Wm. J. Gies reported upon the changes which may occur in lymph after the administration of protoplasmic poisons. Quinin did not interfere with the usual influence of dextrose although it did suppress the action of leech extract. The results with dextrose, therefore, indicate that the increase in the quantity of lymph following its injection in large quantity is due mainly to physical factors. In the case of leech extract, on the other hand, there is an interference with the action of the physiological factors that appear to be responsible for the changes usually brought about by this lymphagogue. That the increase in the amount of lymph after large quantities of dextrose have been injected is not due primarily to increased capillary pressure, as is held by Cohnstein and Starling, was shown in one of the experiments in which quinin caused the death of the animal, and yet from which the lymph continued to flow for three hours. After injecting arsenic, which is said to very greatly increase the permeability of the blood vessels, especially those of the portal system, there was little in the flow and character of the lymph resembling the usual effect of lymphagogues. It appears, therefore, that Starling's hypothesis of increased capillary permeability does not fully account for the action of lymphagogues, and that the mechanical theory of lymph formation fails as long as it does not explain the most striking phenomena of the process—those following the injection of Heidenhain's lymphagogues or Asher's 'liver stimulants.' The physiological theories of Heidenhain and Asher would explain them.

Professor Frederic S. Lee said that the duration of the life of voluntary muscle in mammals after the death of the individual has not been well known. Under the author's direction, Messrs. Adler and Bulkley have been investigating this in cats and rabbits. In each experiment the animal was killed, a particular muscle was excised and stimulated by electric shocks at five-minute intervals, and the resulting contractions were recorded. The muscles used were the *soleus* (deep red), and the *tibialis anticus* (pale). Each survived several hours, the maximum for the red muscle being 14 hours and 37 minutes, and for the pale, 12 hours and 20 minutes. It is known that, in comparison with white muscle-fibres, red fibres contain relatively more sarcoplasm, which is nutritive in function, and relatively less fibrillar substance, which is the contractile part. This may perhaps account for the longer survival of the red muscle. So far no constant difference in duration has been observed between the cat and the rabbit. In both the red and the pale muscle the decrease of irritability was gradual, but occasionally in the *tibialis* there was a sudden fall at the end of about one hour, the irritability then continuing at a low ebb for hours but with a gradual decline. The sudden fall may have been due to the early death of the white fibres, which intermingled with red ones, occur in the pale muscle. Besides the theoretic interest, the above results have a practical bearing, since they show that mammalian muscle can readily be used for experimental purposes in the physiological laboratory. This is now being done at Columbia University.

Professor Henry F. Osborn reported upon

recent additions to the American Museum from the Cope collection through the munificence of President Jesup. (For a fuller account see SCIENCE, N. S., XI., p. 77.)

Bashford Dean described the condition in seven eggs of *Myxine glutinosa* which he had received from Professor A. E. Verrill. These had been collected in 1880 on the Newfoundland banks in water of 90 and 150 fathoms. The egg membranes were regarded as more specialized than those of Bdellostoma.

DISCUSSION AND CORRESPONDENCE.

DO THE REACTIONS OF THE LOWER ANIMALS AGAINST INJURY INDICATE PAIN SENSATIONS ?*

IN a posthumous article with the above title by the lamented Professor Norman is contained the chief substance of what was to have been his doctorate thesis. It comprises new facts and a statement of those that are old in a way which will interest especially the psychologists and gratify to no small degree the physiologists—or some of them. While the author answers the titular question in the negative, as his main thesis, 'lower animals' indicates for him only those species up to and including the flounder. Moreover, the paper is remarkably free from opinions based on analogy, the evidence being weighed as its author thinks solely for what it is worth and regarding the particular species experimented upon alone.

The report begins with a proper adverse criticism of that mode of argument in a circle which bases presumption as to the mode of consciousness concomitant to movements, on these same movements taken as expressive of certain modes of consciousness. He follows rather the purely physiological method of considering movements as the immediate consequence of physical stimulation, the psychic factor not entering the problem at all. Certain experiments seem to the author to prove the correctness of this point of view.

* By the late Professor W. W. Norman, University of Texas, with Additional Note by Jacques Loeb. *American Journal of Physiology*, Vol. III., No. VI., 1 Jan., 1900. Pp. 270–284.

The most striking and classic of these experiments were made on the common earthworm (*Allolobophora*). If such a low animal be divided at its middle transversely, only the posterior half shows those squirming and jerking movements which, anthropomorphically viewed, seem to indicate pain; the anterior half (containing the brain) crawls, as ordinarily, away. Now if each of these halves be halved, again the posterior segment of each squirms while the anterior halves crawl away. This same process may be continued with precisely like result until the pieces are no longer large enough to crawl independently. This striking phenomenon is explained in part by the two sets of muscular fibers in the worm, one longitudinal, causing the squirming and jerking, and the other circular, which produce the crawling. Why in the posterior segments the former set should be initially stimulated and in the anterior the latter set, Professor Norman says he does not know. For its purpose the experiment seems conclusive. Similarly, if a swimming leech be cut in two, both parts, after a pause, swim off as if nothing had happened. Like events take place with other species of worms, the anterior or brain part being regularly that undisturbed by the extraordinary stimulus.

The abdomen of a hermit crab may be cut in two without any 'but a very slight response' from any remaining movable organ. *Limulus* stops a few seconds when four or five abdominal segments are cut away, then proceeds quietly breathing as before. Its order of events is regularly: cessation of breathing, flexion of abdomen, pause, extension of abdomen, respiratory movements. *Geophilus* cut in two in the middle continues its crawling, the front half going forwards and the rear half backwards. Millipedes divided while walking do not hasten nor stop nor jerk. Dragon flies lose parts of their abdomens without any appreciable change in position. As was long ago pointed out, bees continue to eat when their abdomens are cut way during the process.

Lastly, sharks and flounders, provided a current of water circulate through their gills, will allow the most tedious and deep-going cutting operations on their heads without the slightest appreciable movement indicative of pain or even of sensation.

In the 'additional note,' Professor Loeb points out as the two chief results of the investigation: "(1) In a great number—perhaps the majority—of lower animals injuries cause no reaction which might be interpreted as the expression of pain sensations. (2) In the limited number of cases where injury is followed by motions which have been considered as the expression of pain sensations (as in the case of worms) a closer analysis shows that this interpretation is unjustified."

This article is noteworthy not least for what it neither says nor implies, namely, that animals other than those there considered probably do not feel pain. Notwithstanding this most commendable modesty of opinion on the part of its author, certain considerations present themselves therefrom, which are of too great moment both to psychology and to physiology to remain unanswered. The problem may be properly considered as insoluble—yet well worthy of debate. It will not be maintained that these animals do experience pain when they are injured, *but only that they may for all that experiments prove to the contrary.* Analogy and reasonable presumption are our only methods when inexperiencable sensations are in question and the former of these at least works both ways.

The lowness of the investigator's subjects in the animal 'scale' is worthy of preliminary notice. On this account it would at first sight seem that the author's and Dr. Loeb's opinion was more valid, on the common supposition that 'so low a grade of consciousness could not include actual, stinging pain.' The nervous systems of these worms and echinoderms and fishes seem undoubtedly too simple to allow of the presence of organs for pain such as on the whole seem probable in man and his congeners. The highest, highly differentiated animals require painful sensations as a means teleologically protective of their different organs; in the lowest orders, on the other hand, this need does not exist, for their relative simplicity of plan makes possible the regeneration of any lost part or organ or even the perfecting of an individual from a part artificially cut off from another individual. It is therefore extremely reasonable even from the pan-psychistic viewpoint to suppose that organs of pain would be undeveloped in these very lowly forms. The simplicity of neural structure in these orders makes it certain almost that much, present in higher forms as organs correlated to consciousness of various modes, would here be lacking. The worm and the starfish, simply because they are in a less degree, physiologically speaking, individuals than is a dog or a man, require fewer of those organs on which a continuance of individuality depends. But while this is so, perhaps, the sort of pain under discussion is not man's degree of pain, but rather that grade of painful consciousness proportionate to the needs of the animal in which it may or may not be experienced. The difference is not one of kind but one of degree, and a degree suitable to the biologic needs of the particular species may be present, commensurate not to the complexity of a nervous system even, but perhaps only to the necessity of the preservation of individuality—a necessity in some of the species experimented on obviously exceedingly small.

In view of the great similarity functionally between the neural structures of the higher animals and those of man, no one perhaps would seriously deny consciousness to, say, an elephant or an ape. To damaging stimulation these animals react much as does man, but it is a quite gratuitous presumption that the earthworm and the flounder would react to a destructive excitation in a manner even comparable to that in which these higher forms react. To suppose this would be to employ again only a sort of the objectionable anthropomorphism. Because the elephant or the cat with a remarkably elaborate system of innervated, muscled, and jointed limbs, reacts in a characteristic way to injury, there is no reason to expect the Nereis or the starfish to react similarly in any sense. The rabbit even, with essentially all the motor mechanism which man possesses, 'expresses' pain often times only by attempts to get away and by an increase in the breath-rate; indeed this dyspnœa is often the physiologic anæsthetizer's only sign that more ether is urgently demanded. It is not necessary then because the lowest forms of animals do not act as mammals act under injury to presume on that account an absence of that degree of unpleasant consciousness which corresponds to the higher animal's pain. One might *à priori*, from difference in structure and in function both, expect wholly different reactions to stimuli or even none at all. Qualitatively as well as quantitatively the reactions of any two genera may differ to any indefinite degree.

Again that relative deficiency of simplicity of neural organs, natural to the low orders, may be and presumably is correlated with a like deficiency in the duration of the sensations represented by these organs. The time of continuance of a sensation occasioned by a momentary stimulation is perhaps determined by the number and extent of something comparable to association-currents running either between different parts of the neural unit or between these units extended spatially, or both. The former of these conditions may be simpler in the lowest orders, and the latter wholly or at least partly lacking. 'Reverberation,' in a word is less, the simpler the nervous organ. Professor Norman expressly noted in most of his experimental reports a period of quiet on the animal subject's part, representing nervous shock. It is a pure presumption to conclude that such a condition is not 'painful' to the animal. In all the higher animals severe pain is essentially asthenic in its effect on the organism. Limulus, cited by the writer, shows this especially well, and furthermore presents yet further evidence of painful or destructive sensation in the extreme abdominal flexion, the general concomitant of pain, noted in the experiments. This depressing period being past, and the perhaps only pseudo-individual being by the injury in no way incapacitated for its customary movements (because of lack of coördinating neural mechanism), these movements soon proceed as if nothing had happened, as indeed perhaps nothing had happened to more than an insignificant independent portion of the quondam individual.

Another consideration, quite old but on that account not less reasonable as it seems to the present writer, may be based on the biologic principle that nature does not act by leaps, that continuity is the all-pervading principle of evolution and so of psychophysical development. Man undoubtedly has consciousness and at times pain; the lowest organism has a minimum, but always some, of both, 'consciousness,' here indicating experience correlate with mechanical function, and 'pain' that sort of disadvantageous experience correlated with injury to the biologic egotism of the individual—very general terms, but therefore the more useful. Between these two zoologic extremes, the maximum and the minimum of developed life, all animal life has place and has accordingly, from this theoretical point of view, some degree or other of what, for want of a better term, is called pain. Each individual in its degree, be it man's degree or the earthworm's, has feeling, from this the philosophical view point, even as it has motion through space or within its organs. Let one who is disposed to deny this say with what genus sensation ends as one looks down the closely crowded scale of life—is it between man and the monkey or between the alligator and the flounder? However large the empirical gap at present between any two genera may be, the problem is not altered, for like biologic principles actuate them all, and strongest of these principles normally is the preservation of the individual. To this end, perhaps, pain developed, and to this end it everywhere, in the long run, works. This proposition is more than a mere speculative presumption, for observation inductively originated it and continually supports it. To get beneath it were to solve at length the great problem of Job, were to go deeper than empirical science can. It is a principle too firmly fixed in the philosophy of biology, so to say, to be shaken by the necessarily wholly negative result of experimentation where the conditions are so far from those of man, the judge.

PLANT MATERIAL FOR LABORATORY USE IN THE SCHOOLS.

For more than a year there has been offered through the Ithaca Botanical Supply Co. plant material suitable for laboratory use in first courses, and for demonstrations of some of the organs and processes which it is rather difficult for beginning students to prepare. This work was undertaken at my suggestion by some students who were in need of financial assistance in their laudable endeavor to obtain a college education. It was undertaken both for the purpose of affording some aid in this way, and also for the purpose of assisting teachers and schools, especially secondary and normal schools, in the supply of material which is often difficult to obtain.

It should perhaps be stated that neither I, nor the botanical department here, has any official connection with, nor financial interest in, the scheme. At the same time I have taken a lively interest in the work in order to be assured that the material and the preparations should be of the first order. The persons who make the preparations are thoroughly familiar with modern methods and have attained a high degree of skill in preparing them. The permanent slides showing sexual organs and sexual processes in plants of the different groups are excellent and very beautiful. I am quite sure that those who are familiar with good technique will be quite surprised at the high degree of excellence presented in these slides, and certainly they represent the structures in a strikingly accurate manner. They put up in addition to other material, a 'high school set.' Persons or schools desiring further information can obtain a price list by addressing 'The Ithaca Botanical Supply Co.,' Ithaca, N. Y.

GEO. F. ATKINSON.

DO FISHES REMEMBER?

A RECENT paper* by Professor L. Edinger, entitled 'Haben die Fische ein Gedächtniss,' is primarily a statement of the conclusions which its author has reached as a result of his questionaire, 'Do Fishes Remember?' sent out in 1897. These conclusions are prefaced by some discussion of comparative psychology in general and some account of the sense-powers of fishes. The former is judicious but not new; the latter is convenient though not complete. Dr. Edinger is inclined to accept the decision that fishes do not hear sounds, though he seems not to know of the experiments of Dr. F. S. Lee, experiments more conclusive than any he reports.

Dr. Edinger's question as to memory is not about the existence of certain feelings of a thing as having been experienced before, but about the possibility of permanent associations, of after-effects of experiences. He asks concerning the fish nervous system, "Is this apparatus capable of in any way preserving impressions made upon it; do there exist after-effects due to previous experiences?" p. 16. Or, in other words, "Can impressions which are new to the animal, gain an influence on its activities; especially can they preserve this influence for a considerable time?" p. 17. He decides in a rather half-hearted way that they can, on the basis of the evidence obtained from the answers to his questionaire and elsewhere. He summarizes this evidence as follows: "(1) The inborn impulse to flee can be lessened by the animal becoming accustomed to impressions which formerly frightened it, but this tameness is lost if new stimuli enter into the experience. The impulse to flee can also appear in the presence of stimuli which have never been present before. Animals become afraid. By habit the sight of the one who feeds them may take the place of the optical or chemical stimulus which ordinarily leads to the act of feeding" p. 28.

Dr. Edinger's limitation of fishes' powers of forming associations and being influenced by them more or less permanently, to the single cases of tameness, fear and associations between the feeder and feeding, is misleading. It is no characteristic of fishes' mentality to form such habits rather than others. The prominence of such in the answers to the questionaire is due, not to the mental constitution of the fish, but to the interests of the observers. As a matter of fact the questionaire proceeding seems a very awkward way of answering the question about the permanent effects of novel experiences. One can, as has been shown in the December number of the *American Naturalist*, get direct evidence of the fact and demonstrate it to a class in the space of five hours.

Although familiarity with animal psychology proper and a bit more ingenuity might have

*Reprinted from *Allgemeinen Zeitung*, München, 21 und 23 October, 1899.

made Dr. Edinger's work more effective and his presentation much briefer, one cannot help feeling great satisfaction at seeing an eminent neurologist realize the value of comparative study by psychological as well as morphological methods. One must also admire the caution and thoroughness with which Dr. Edinger examines animal behavior. Above all one rejoices to see a piece of work in comparative psychology which presents facts without quarreling over the meanings of words.

Columbia University.

THE GERMAN CONSULAR SERVICE.

Mr. Richard Guenther, Consul General of the United States of Frankfurt, writes to the Department of State that the 'seniors' of the Merchants Association of Berlin have addressed a memorial to the Prussian Secretary of Commerce, and at the same time to the Chancellor of the German Empire, which appears to be in response to an inquiry from the Secretary of Commerce, and states what reforms in the German consular service are deemed necessary. The following is a synopsis of the somewhat lengthy document: The main duty of the consul should be to make careful and detailed reports concerning economic occurrences in his consular district. These reports should give not only the figures of the exports and imports, but should also deal with the development of the commerce and the home industries of the country. The consul should be able to point out these conditions upon his own initiative, as well as in response to inquiries from home. He should be well informed about commercial matters at home, as well as in touch with the business world of his district. Means should be at his disposal for travel and he should be compensated for services rendered. Knowledge of the language of the country, as well as of the leading languages of the world, should be of prime consideration. The promotion system of Great Britain should be followed, whereby consuls are transferred between countries where the same languages and similar economic conditions prevail, so that transfers of a consul from China to Russia and thence to Spanish America, for example, should be avoided. Reports concerning the commerce of the foreign country should give comparisons with previous years and be published at home in such a manner as to reach all interested. The letter says that these requirements are more or less realized in foreign countries. The consuls of the United States of America especially have rendered very useful services to the commerce and industries of their home country and have furnished proof that the establishment of commercial consulates bears rich fruit, in spite of the fact that a consul can hardly acquire such special knowledge of trade conditions in the several branches as an agent of some business house. The letter endeavors mainly to show the great desirability of substituting the large number of German 'Wahlkonsuln'—*i. e.*, German merchants resident in some foreign country who act as consuls —by regularly paid consuls, who will give their whole time to their consular duties, and states that a reform is expected mainly from an increased and improved service in the regular consulates, recommending the appointment of commercial attachés to the important consulates, as has already been done at Chicago, Buenos Ayres and Constantinople. It is recommended that the qualifications for appointment as consuls should be of a more practical nature and not so much the mere knowledge of law. The letter also calls attention to the great usefulness of the Philadelphia Commercial Museum.

EDUCATION IN THE UNITED STATES.

The United States educational exhibit at the Paris Exposition will include a two-volume work entitled 'Education in the United States,' which has been planned and edited by Professor Nicholas Murray Butler of Columbia University.

The work consists of nineteen monographs, which, taken together, give a complete view of the present educational activity of the United States. It is proposed to present copies of the work to the leading governments, public libraries and educational institutions of the world, and the public will be given opportunity to purchase copies at a moderate price.

The several monographs which constitute the work, and their authors, are as follows:

1. Educational Organization and Administration—Andrew Sloan Draper, president of the University of Illinois, Champaign, Ill.

2. Kindergarten Education—Susan E. Blow, Cazenovia, New York.

3. Elementary Education—William T. Harris, United States commissioner of education, Washington, D. C.

4. Secondary Education—Elmer Ellsworth Brown, professor of education in the University of California, Berkeley, Calif.

5. The American College—Andrew Flemming West, professor of Latin in Princeton University, Princeton, N. J.

6. The American University—Edward Delavan Perry, Jay professor of Greek in Columbia University, New York.

7. Education of Women—M. Carey Thomas, president of Bryn Mawr College, Bryn Mawr, Pa.

8. Training of Teachers—B. A. Hinsdale, professor of the science and art of teaching in the University of Michigan, Ann Arbor, Mich.

9. School Architecture and Hygiene—Gilbert B. Morrison, principal of the manual training High School, Kansas City, Mo.

10. Professional Education—James Russell Parsons, director of the college and high school department, University of the State of New York, Albany, N. Y.

11. Scientific, Technical and Engineering Education—T. C. Mendenhall, president of the Technological Institute, Worcester, Mass.

12. Agricultural Education—Charles W. Dabney, president of the University of Tennessee, Knoxville, Tenn.

13. Commercial Education—Edmund J. James, professor of public administration in the University of Chicago, Chicago, Ill.

14. Art and Industrial Education—Isaac Edwards Clarke, bureau of education, Washington, D. C.

15. Education of Defectives—Edward Ellis Allen, principal of the Pennsylvania Institution for the Instruction of the Blind, Overbrook, Pa.

16. Summer Schools and University Extension—Herbert B. Adams, professor of American and institutional history in the Johns Hopkins University, Baltimore, Md.

17. Scientific Societies and Associations—James McKeen Cattell, professor of psychology in Columbia University, New York.

18. Education of the Negro—Booker T. Washington, principal of the Tuskegee Institute, Tuskegee, Alabama.

19. Education of the Indian—William N. Hailman, superintendent of schools, Dayton, Ohio.

EDUCATION ADMINISTRATION IN THE STATE OF NEW YORK.

IN his annual message to the Legislature, Governor Roosevelt refers to the proposed reorganization of the State of New York and the Department of Instruction as follows:

The University of the State of New York, with its Board of Regents, is an institution peculiar to this Commonwealth, and one now venerable with its 116 years of history. Its exercise of authority over higher education has been of very great public service, and its methods and standards have exercised a wide influence for good upon those of other States. These facts have led to the adoption, by the people, of an amendment to the constitution of the State, whereby the University itself and its organization under a Board of not less than nine regents, has been provided and safeguarded in the organic law.

The Department of Public Instruction, on the other hand, concerned chiefly with the supervision of all the free common schools of the State, supported by public taxation, has grown to a vast importance; for the number of children of school age in the State has largely increased, and nine-tenths of them attend no other institution than the public school. The work done in both departments has been, in the main, excellent and needful to be done; they are amply worthy of the confidence and continued support of the people. But that their work could be done better, if the two systems were unified, is a proposition hardly open to question. The problem has been not whether unification were desirable, but by what means this end was to be attained.

From the point of view of the public interests, it is neither desirable nor practical merely to extend the jurisdiction of either department over the other. The University convocation, at its annual meeting in July, 1899, requested the Governor to appoint a commission for the purpose of recommending a practical plan of unification, and in accordance with this suggestion the following commission were appointed:

Frederick T. Hollis, Daniel H. McMillan, Judge Joseph Daly, William Kernan, Robert F. Wilkinson, and the Secretary of the Board of Regents, and the Assistant Superintendent of Public Instruction. All were men of the highest standing, of trained capacity, and specially interested in the whole subject. I cannot too heartily thank them for their invaluable and wholly disinterested labor for the public welfare.

This commission, after careful consideration, has arrived at suggestions embodied in a report suggesting statutory changes which, if adopted by the Legislature, will give effect to the system which they recommend. What they propose is the creation of a Department of Education, including both the University and the Department of Public Instruction, of which a single officer, known as the Chancellor of the University, shall be the responsible executive and administrative head. The University is, of course, continued, and has its oversight extended to cover the entire field of education, so that its real authority and opportunity for public service will be much increased.

The plan proposed is simple, effective, and wholly free from political or partisan considerations. It deserves the cordial support of all friends of public education, and this means of every patriotic citizen of the State.

It is impossible to exaggerate the importance of the interests involved, or the importance of considering them solely from the point of view of the general welfare of the State.

INDIAN UNIVERSITY FOR RESEARCH.

Consul Fee writes from Bombay under the date of November 1, 1899, to the Department of State as follows:

The conference which has been sitting at Simla, the hot-weather capital of India, considering the scheme for a research institute, has about completed its labor. Its recommendations will be submitted to the government of India for sanction, and later will be put into legal being by proper legislation.

The inception of the idea of this institution is Mr. Tata's, a wealthy resident of Bombay, whose public spirit and munificence has made its creation possible.

It is to be named the 'Indian University of Research.' It will be unlike all other universities of India, in that it will neither be an examining body nor bestow degrees, but will grant fellowship to distinguished students and graduates, and afford them facilities for research and investigation in the broadest sense possible. It will have a university court, consisting of a chancellor, a vice-chancellor, one member to represent the supreme government of India, one to represent each of the eight local governments, one for each of the five existing Indian universities, one to represent Mr. Tata, and one to be added for any benefactor who may subscribe not less than 15,000 rupees.

The site, the question of which gave rise to no little discussion, was finally granted to Bombay, with Bangalore, the chief city of the native state of Mysore, as a second choice. The fact that the Mysore government had offered to donate a site and a handsome contribution to the building may have been an attraction.

It is recommended that this new university coöperate with existing institutions by giving assistance to original scientific research where this work is now in any way hampered or curtailed.

The conception of this institution is as broad as its ultimate development will be vast. It will give a livelier tone to higher education in India, and be a noble monument to its founders and promoters.

SCIENTIFIC NOTES AND NEWS.

Mr. J. B. Hatcher has been appointed chief of the department of vertebrate paleontology of the Carnegie Museum, in place of Dr. Wortman, who has resigned. Dr. Wortman will undertake work on the collections made by the late Professor Marsh for the Peabody Museum, Yale University.

Sir Robert Ball, F.R.S., was elected president of the Mathematical Association for the ensuing year at the annual meeting of the Association at University College, London, on January 27th.

The Prince Regent of Bavaria has conferred the order of St. Michael on Dr. Nansen.

The address at the commencement exercises of the University of Michigan next June will be delivered by John M. Coulter, Ph.D., head professor of botany in the University of Chicago.

DR. GEORGE F. BECKER, of the Geological Survey, who was recently sent by the government to the Philippines to report on the geology and mineral resources of the islands, has returned to Washington.

THE death is announced in Berlin of Dr. W. Hauchecorne, director of the School of Mines.

WE also note with regret the death, on January 13th, of Dr. J. W. Gunnings, professor of chemistry at Amsterdam, at the age of 72 years; of Dr. Peter Waage, professor of chemistry at Christiana, at the age of 57 years, and of General Alexis de Tillo, of St. Petersburg, known for his work in geography and meteorology.

THE mineralogical museum of Columbia University will be named after the late Thomas Eggleston, long professor of mineralogy and metallurgy at the University, to whose gifts and efforts the museum is chiefly due.

PROFESSOR G. H. PARKER, on January 29th, lectured before the New York Academy of Sciences, under the auspices of the Section of Biology. The title of the lecture was 'The Neurone Theory in the Light of recent Discoveries.' The lecturer gave a summary of the development of our knowledge of the histological structure of the nervous system, and contrasted with the neurone theory as widely understood that of Apathy's, which declares the absolute continuity of the nervous system by means of the fibrillæ in the nerve cells and fibers as demonstrated by his method of technique. The lecture was closed by a criticism of Apathy's interpretation of his preparations.

DR. EDWARD THORNDIKE, of Columbia University, gave a series of five lectures before the course in General Biology at the University of Chicago, February 4th to 9th. One of these was also open to all members of the University.

PROFESSOR T. H. MORGAN, of Bryn Mawr College, will repeat the course of lectures given at Columbia University at the University of Chicago, February 19th to 23d.

ON February 8th, Professor H. H. Turner, F.R.S., Savilian professor of astronomy in the University of Oxford, gave the first of a course of three lectures at the Royal Institution on 'Modern Astronomy.' On March 22d, Mr. H. J. Mackinder will deliver the first of a course of three lectures on 'Equatorial East Africa and Mount Kenya,' in the place of Mr. E. A. Fitzgerald, who is unable to deliver his course of lectures owing to his departure for South Africa.

LARGELY through the generosity of Mr. W. F. E. Gurley, formerly State Geologist of Illinois, the University of Chicago has come into the possession of an exceptionally valuable collection of paleozoic fossils. The making of this collection has been the life work of Mr. Gurley and it is undoubtedly the best existing collection of the paleozoic fossils of the interior States. It also contains a large amount of excellent material from other regions. The collection is estimated to contain 15,000 species, and several hundred thousand specimens. With this collection as a nucleus, the University of Chicago will be in position to build up one of the most valuable collections of paleozoic fossils in America.

MR. MORRIS STEINERT has given to Yale University his collection of historical musical instruments. It includes more than 500 pieces, including some of great value, representing the development of the piano and violin. The collection also includes musical manuscripts and original musical compositions.

BY the will of Mme. Beaucourt the Geological Society of France receives 40,000 fr., the income of which is to be used for research work.

IT is stated in the *Scientific American* that the sum of $7,550 has been given by Professors Haeckel, Conrad and Fraas, to be awarded for the best essays submitted on the application of the Darwinian theory to international political development and legislation. The essays must all be submitted prior to December, 1902.

THE American Section of the International Association for Testing Materials, of which Professor Mansfield Merriman, of Lehigh University, is chairman, has received contributions to its publication and research fund amounting to $655.

WE learn from the *National Geographic Magazine* that the French government will erect a meteorological observatory on a hill near Tonkin.

THE Weather Bureau proposes to extend its service by establishing stations at all the Mexican Gulf ports between Tampico and Progreso.

A TELEGRAM has been received at the Harvard College Observatory from Professor Kreutz, at Kiel Observatory, stating that Comet *a* 1900 (Giacobini), was observed by Javelle at Nice, February $3^d.2893$, Greenwich Mean Time, in R. A. 2° 49′51.″0, and Dec. —6° 40′ 10″:

Daily motion in R. A. — 39′
" " " Dec. + 25″

A CABLEGRAM to the daily papers reports that there were 400 deaths at Bombay on February 5th, more than on any day since the first outbreak of the plague.

THE congregation of the University of Chicago, at its meeting on January 3d, adopted a resolution to the effect that the official publications and journals of the University should use the simplified spelling recommended by the National Educational Association. This action was, however, overruled by a vote of 20 to 16 by the Faculty Senate.

ACCORDING to the daily press, the cable sounding ship *Nero* which arrived at Honolulu on January 29th, while between Guam and Manila, made the deepest ocean soundings that have yet been recorded. She found a large area over which the soundings showed 5260 fathoms, about 260 fathoms more than had ever been found before. This area was named Nero's Hole.

THE second annual meeting of the New England Association of Chemistry Teachers was held at the United States Hotel, Boston, on February 3d. Mr. Charles A. Pitkin, of South Braintree, reported for the committee on physiological chemistry, and Mr. Irving O. Palmer, of Newton, for the committee on new apparatus and methods, while Professor Theodore W. Richards, of Harvard University, told of Harvard requirements for admission in chemistry. Mr. Rufus P. Williams, of Boston, was elected president, and Mr. H. J. Chase, of Newton, secretary, for the coming year.

THE *Electrical World* states that the English army surgeons' employment of the Röntgen rays in field surgery has proved most successful, and has met with the highest commendation. Orders have been received for a fresh equipment and skilled operators, and before February it is likely that every column at the front will be furnished with a Röntgen ray outfit. Wireless telegraphy is also rapidly gaining ground. Marconi outfits are being installed on three British vessels destined for active service, as well as on the passenger steamers in the English Channel.

AT a New York State Civil Service Examination to be held on February 24th, the position of assistant in geology in the State Museum, will be filled. The salary of this office is $900. It is desired that candidates shall be graduates in civil or mining engineering.

A VACANCY exists among the second-class assistantships in the Geological Department of the British Museum, owing to the removal of Professor Gregory to Melbourne. Admission to these posts is by Civil Service examination in general and special subjects, after nomination by the trustees. The maximum limit of age has recently been lowered to 25 years. The British Treasury Department has, however, the power of appointing persons over this age and without examination, should a strong recommendation to that effect be made by the trustees. It is said, however, that such appointments have always been highly unpopular with the working staff.

ACCORDING to the bill now before Congress, providing for a Department of Commerce with a Cabinet officer, the Patent Office is removed from the Interior Department and placed under the proposed Department of Commerce.

A BILL has been introduced into the New York Legislature appropriating $200,000 for the construction and equipment of suitable buildings for carrying on the work of promoting knowledge throughout the State in forestry and agricultural lines by Cornell University.

THE president of the British Board of Agriculture has appointed a departmental committee to inquire and report as to what regulations may with advantage be made by the

Board of Agriculture, for determining what deficiency in the normal constituents of genuine milk or cream, or what addition of extraneous matter or proportion of water, in any sample of milk (including condensed milk), or cream shall raise a presumption that the milk or cream is not genuine. The committee will consist of the following gentlemen: Lord Wenlock, (chairman), Mr. George Barham, Mr. George Cowan, Major Patrick George Craigie (an assistant secretary of the Board of Agriculture), Mr. S. W. Farmer, Mr. Shirley F. Murphy, M.D., Professor Thorpe, F.R S. (principal chemist of the Government Laboratories), and Mr. J. Agustus Voelcker, Ph.D. Mr. Robert Henry Rew, of the Board of Agriculture, will act as secretary to the committee.

AN effort is being made by the New York Fish, Game and Forest League in New York State to secure the establishment of a State Biological Station. Professor H. A. Surface, chairman of the biological committee, writes that its purpose would be the making of investigations and practical experiments (*a*) to determine the nature, habits, food, and needs of the fish, game and insectivorous and song birds; (*b*) to determine the causes of their decrease; (*c*) to determine what measures can be taken to reduce their enemies, increase their natural food supply and shelter, and secure such natural or modified conditions as should lead to their abundance throughout the State; (*d*) to propagate not only the desirable creatures named above, but also their natural food supply; (*e*) to study and experiment with the best methods of introducing beneficial species, to show what measures can be taken to help them to become acclimated, and to provide for their winter feeding and shelter; (*f*) to obtain material for publication; (*g*) to obtain facts upon which proper legislation can be based to secure the effective protection and maintenance of desirable species and the destruction of obnoxious kinds; (*h*) to obtain facts that may be useful to teachers of nature study, natural history, biology, botany, zoology, ornithology, ichthyology or forestry in the State. Another important feature will be the preparation and labeling of collections of specimens (especially fishes and other aquatic and semi-aquatic animals) for schools of the State, which will stimulate scientific research and facilitate better methods of science teaching.

A MARINE laboratory and museum will be opened at the University of Berlin on the first of April.

A SECOND edition of the Botanists Directory, published by I. Dörfler, Vienna, is in preparation. The publisher will be glad to receive the names and addresses of all botanists, especially those whose names do not appear in the first edition, as well as information concerning botanical gardens and societies concerned with botany.

WE learn from the *London Times* that the report by Sir William Crookes, F.R.S., and Professor Dewar, F.R.S., on the composition and quality of daily samples of the water supplied to London for the month ending December 31, 1899, states that of the 192 samples examined by them during the month, all were found to be clear, bright, and well filtered. The rainfall at Oxford during the month was 1.30 in. The average for the past 30 years is 2.10 in.; this leaves a deficiency of 0.80 in., bringing the total deficiency for the year up to 4.54 in., or 17.6 per cent. The general supply has been admirable from a bacteriological point of view. During the year they examined 4792 samples of London water bacteriologically, as compared with 3590 and 3249 respectively in the two previous years. They also made 2456 chemical analyses of London waters, making a total of 7248 samples examined. During the first six months the Thames-derived companies clear-water wells contained on the average 32 bacteria per cc., while the New River and River Lea supplies contained respectively 18 and 25. During the second six months the number of bacteria in the waters from the three were respectively 22, 12, and 14. These results show that during the year effective filtration of the London waters has been properly maintained. The report adds: "When we consider that a water containing about 100 bacteria per cc. in the clear-water wells would be regarded by the highest authorities as properly filtered, we see that the London supply must be considered exceptionally good."

THE *British Medical Journal* states that there are now eight Pasteur Institutes in France; arranged according to the dates of their establishment, they are those of Paris, Algiers, Tunis, Montpellier, Marseilles, Bordeaux, Lille, Lyons. The last was opened on the first day of this year. There are five like institutes in Italy (Bologna, Milan, Naples, Palermo, Turin), two in Austria-Hungary (Vienna and Buda-Pesth), seven in Russia (St. Petersburg, Moscow, Samara, Kharkof, Warsaw, Odessa, Tiflis), two in the Ottoman Empire (Constantinople, Aleppo), one in Roumania (Bucharest), and one in Malta.

'Variations and Regeneration in Synapta inhaerus' on page 178 of the number of Science for February 2, 1900, should have the name of the author, Professor Charles L. Edwards, attached to it.

UNIVERSITY AND EDUCATIONAL NEWS.

Plans for a botanical laboratory to cost over $100,000 have been submitted to the Senate of Cambridge University.

The new wing of the engineering laboratory at Cambridge University, erected in memory of the late Dr. John Hopkinson by his widow and family, was formally opened on February 2d by Lord Kelvin; and at the same time a portrait of Dr. Hopkinson was unveiled.

St. Lawrence University has recently received a gift of $24,000 from a friend of that institution.

The Massachusetts Institute of Technology offers a new course in landscape architecture which, as provisionally laid out, includes in the second year horticulture, elementary architectural design, shades and shadows, perspective, freehand drawing, surveying, topographical drawing and dynamical geology, with the usual general courses in physics, language and history. In the third year the same general lines of work will be followed, with work in horticulture at the Arnold Arboretum, architectural and landscape design, architectural history, freehand drawing and pen and ink, stadia and plane table surveying, curves and earth-work, highway engineering and structural geology. In the fourth year, landscape architecture and design and horticulture will be the main features, with courses in sanitary engineering and drainage, building stones and sanitary science, history of ornament, life class, modeling, pen and ink, water color, specifications and working drawings and business relations. An arrangement has been made with the director, Prof. C. S. Sargent, of the Arnold Arboretum, by which students will receive a part of their instruction there, particularly in all that relates to planting and the use of plants and trees. With this work at the Arboretum will be combined a series of excursions to neighboring parks and country places in order to study examples of planting and design. The special instruction in landscape design will be conducted by Mr. Guy Lowell a graduate in the class of 1894, who has since taken the diploma of the École des Beaux Arts with distinction, and has made a special study of landscape architecture in Europe.

The course of landscape architecture, at Harvard University, the establishment of which we recently announced, has been placed under the direction of Mr. Frederic Law Olmsted, Jr. He will be assisted by Mr. Arthur A. Shurtleff.

The Techincal Education Board of the London County Council offers two scholarships of £150 each to teachers in schools. They are tenable from Easter to Christmas 1900, and enable the holder to visit the continent and study methods of teaching modern languages in commercial schools.

The foundation of a chair of American Archæology at the University of Berlin by the Duke of Loubat, has given a great impetus to the development of the teaching of anthropology at that University. Recently it has been announced that Adolf Bastian has been made Professor Ordinarius of Ethnology. This has been followed by the announcement of the appointment of Dr. Felix von Luschan as Professor (extraordinarius) of Anthropology.

Nichols Knight, Ph.D., of Syracuse University, has been appointed professor of chemistry at Cornell College, Mt. Vernon, Ia.

June E. Downey, A.M. (Chicago), has been appointed instructor in psychology at the University of Wyoming.

MSS. intended for publication and books, etc., intended for review should be sent to the responsible editor, Professor, J. McKeen Cattell, Garrison-on-Hudson, N. Y.

*ARE FURTHER EXPERIMENTS NEEDED FOR DETERMINING THE ATOMIC WEIGHT OF OXYGEN?**

THE precision of experiments on the atomic weight of oxygen has been gradually so much increased that, in some cases, the mean error of a single determination is less than 1 part in 10,000. The agreement of different series of experiments is not so good, but if the work of different experimenters agreed well, the question, how accurately do we really know the atomic weight of oxygen, is not one which we can readily answer. Neither the concordance of the experiments of a given series, nor the agreement of the results of series of experiments by different observers, can excuse us from search for sources of error. All sciences which have to do with measurement afford sufficient instances of the fact that our conclusions are to be received with a certain suspense of judgment. And chemistry well illustrates that he is wise whose assertions regard the possibility of finding at some time evidence to the contrary.

The history of experiment on the atomic weight of oxygen affords an interesting example of the fact that neither the concordance of individual observations nor the agreement of different experimenters proves that a measurement is right. To-

* President's address, delivered before the New Haven Meeting of the American Chemical Society.

ward the middle of the century, Dumas made his classic experiments on the composition of water. The probable error of a single experiment was, in round numbers, 1 part in 400, so that the probable error of the average of the 19 famous experiments was 1 part in 2250. Now, this means that his final value was not likely to differ more than a certain small quantity from the result of the repetition of even a very large number of experiments made in the same way, with the same skill and care. But as to the difference between this result of the 19 experiments and the unknown true value, we are told absolutely nothing by the proposition that the probable error of Dumas' result was 1 part in 2250. It is a commonplace to say, that the calculation of the probable error of a series of experiments does not show how nearly the result approaches the truth, but how near it is to the result of a greater number of similar experiments. It decides, not how nearly we approach the desired goal, but whether it is useful to persevere by the present method of approach. Dumas made 19 observations, and got the value, 15.96, with a probable error of 0.007; that is, if he had made 100 or 1000 experiments, it is unlikely that the final result would not have been between 15.95 and 15.97, and very unlikely indeed that it would not have been between 15.94 and 15.98. But he would never have obtained a value near that which now commands confidence.

It is interesting to recall that there is hardly any instance on record where the judgment of an experimenter as to the degree of approximation to the truth attained in his work has been better justified than in the case of Dumas' classic experiments. As we all remember, towards the end of his work, there was discovered in his own laboratory a source of error, not easy to eliminate, which had affected all his determinations. The amount of the error was not a fixed quantity, and no numerical correction could be applied to the results of observation. Dumas accordingly gave to the public the uncorrected and unmodified results of experiment. But he also stated his opinion as to the degree in which his results approximated, not to the mean of a larger number of experiments of the same kind, but to the unknown and unattainable true value. He expressed the hope that his value would be found not more than one part in 200 from the result of those subsequent experiments which should be thought satisfactory; and it is by just 1 part in 200 that his value differs from that which is now accepted.

So the concordance of Dumas' experiments did not prove that his result was right; neither did the agreement of experiments by different observers. Erdmann and Marchand made eight experiments by a method like that of Dumas, with some modifications. Their result was 15.973, with a probable error of 0.011. This value differs from that of Dumas by less than the sum of the probable errors, so that that agreement is perfectly satisfactory. So, also, Regnault determined the ratio of the densities of oxygen and hydrogen, from which was computed the atomic weight of oxygen as 15.963, with a probable error of 0.004. The results of Dumas, of Erdmann and Marchand, and of Regnault, show a very good agreement. But all of them, and the mean of all of them, we now know to be in error by 1 part in 200.

I adduce this example, somewhat in detail, to enforce the proposition that we must not excuse ourselves from looking for error because observations agree. We have experiments which give the atomic weight of oxygen with a probable error of 1 part in 50,000, but do we know it within 1 part in 1000? Each individual experimenter whose work would now be regarded as free from known and tangible error, agrees fairly well with the mean of all. For instance, Noyes' results show that degree of concordance which would justify us in expecting that, if he were to make 100 or 1000 experiments, his final mean would be as likely as not to be larger or smaller by 1 part in 9500, and his result differs from that which we accept by 1 part in 900. So Cooke and Richards assign a value which is just as likely as not to be within 1 part in 8000 of the result which they would have obtained by multiplying observations; and it differs from that which we accept by 1 part in 1500. But do we know that their means, and the means of all published results taken together, are not in error by 1 part in 900? The concordance of the results of a single experimenter, and the agreement of different experiments, does not justify us in asserting that we do.

In determining the atomic weight of oxygen, it has been somewhat difficult to determine directly all three of the quantities involved, and so to make what Stas called a *complete* synthesis. Berzelius, Dumas, and Erdmann and Marchand, weighed oxygen and weighed water, thus determining hydrogen by difference. More recently, Dittmar and Henderson and Leduc used the same method. Cooke and Richards, and Keiser weighed hydrogen and weighed water, while Rayleigh and Noyes weighed hydrogen and weighed oxygen. Any proceeding which weighs hydrogen directly has a great advantage in precision; different determinations in a given series agree better among themselves, and the series of different experimenters also agree better. But there is also a second, more important advantage. We have reason to believe that the constant errors involved in weighing hydrogen are small, for it is possible to obtain hydrogen with less than $\frac{1}{10000}$ or even $\frac{1}{20000}$ of its weight of impurity. There is no difficulty in weighing oxygen or water with accuracy, so if we weigh hydrogen and also weigh either oxygen or water, we may hope for a near approximation to the true value of the ratio sought.

We may hope, but we cannot *know*. We may believe that our hydrogen is pure, and that there was no error through leakage. But an unsafe stop-cock might make the apparent weight of the hydrogen in a series of experiments seem always smaller than the fact, and might yet leave the individual experiments so concordant with each other as to seem trustworthy.

If, however, we can weigh hydrogen and can weigh oxygen, and then combine them and weigh the water produced, we can at least give a better reason for our hope, if we find that the product is nearly equal to the sum of the components. The manipulation in this case is costly, and is so difficult, and involves so many minute details, that not many have patience and time sufficient for it, so that no great number of such complete syntheses has been made, and these few were made in conditions but little varied. When such complete syntheses shall have been made by different observers, with those variations of apparatus and method which may seem wise to them, we shall be able to judge of the magnitude of the errors to be feared. If such results are not concordant, we shall have much to learn as to sources of error; but we now see some reason to expect that they will not be discordant. However, even if they are not discordant, we are not to excuse ourselves from further study of sources of error.

Before repeating determinations so troublesome, and before studying unknown sources of errors not yet detected, the experimenter should receive all possible assistance from chemical theory and from criticism. For some, that criticism may be most profitable which is friendly and sympathetic; but, for the experimenter, the value of the criticism depends on the knowledge and the acuteness of the critic. Dr. Hinrichs published, some five years ago, a criticism of all determinations and computations of atomic weights since Dumas. As is well known, he is a most strenuous and insistent supporter of Prout's hypothesis. Looking hastily through the volume, there was found, towards the end, evidence that its author was one of those who, some thirty years ago, discerned that which, in the hands of Mendeléeff became the periodic law. It seemed possible that one who had early seen some indications of this law might, perhaps, also have discerned, even if obscurely, some principle relating to atomic weights. I therefore once spent some time and pains in carefully reading the book, and considered at length those passages, which, if any, contained valid criticism of the views which are generally accepted.

Hinrichs believes that the mean of a series of determinations of an atomic weight cannot give the true value sought. This proposition he deduces from a mathematical discussion. He believes that as larger and larger quantities are taken in our analytical operations, the results differ regularly from ideal accuracy; sometimes the difference continually increases as the quantity taken increases; sometimes the difference increases to a maximum and then decreases again. The proper computation of an atomic weight then, according to Hinrichs, consists not in taking the mean of different observations, made with different weight of materials, but in determining the limit towards which the series converges as the weight taken decreases. A good illustration is given: we cannot determine the weight of a new coin by weighing any number of old coins; every coin is worn and therefore light, and the mean weight of any number whatever is therefore necessarily below the mean weight of new coins. But if we weigh old coins and note the date of each, we may take the mean weights for each year separately. If we examine coins enough, these means when plotted as the ordinates with the years as the abscissas, will give us a "fairly regular curve, lowest for the oldest coins, gradually rising towards a *limit* which they would not quite reach. This higher limit would evidently be the mean weight of the new coin."

This is an intelligible proposition. It seemed to me worth while to examine it, for to this proposition one of the most enthusiastic and most active supporters of Prout's hypothesis, a man not lacking in shrewdness or ability or learning, has entrusted the defense of his favorite belief.

He asserts that an atomic weight as determined by experiment is variable, that it depends on the amount of substance taken for the analysis or other operation, and that it varies in a continuous and regular manner. His proposition is, that an atomic weight as determined by experiment is a function of the weight of substance taken. Is there any evidence in favor of it?

I answer, first: Theory does not afford any evidence for it. Hinrichs deduces this proposition from theory by a discussion which is mathematical in form. Whether the proof is sound need not be considered, for his theory does not attempt to show the order of magnitude of the regular and continuous variations which are affirmed to depend on the weight of substance taken, and to show whether they can be separated from the irregular and discontinuous errors due to accident. We are sure that accidental errors exist; we may concede for argument, that regular and continuous variations also exist; but this is far from implying that the actual errors in a given set of experiments will be largely or even perceptibly of the latter kind. Theory shows that there is a diurnal tide in the atmosphere; but theory does not show that the differences noted in a series of ten observations of the barometer at different hours of the day will follow the law of the diurnal tide.

But, secondly: Facts do not agree with the proposition. The accidental errors of the most precise experiments yet made are so much greater than any *systematic* variations, that nothing but accidental variations can be detected. To prove this, let us consider Stas' synthesis of silver nitrate from pure silver. This is one of the most important determinations ever made; Hinrichs has discussed it twice in his volume; he asserts that the ratio of silver nitrate to silver found in each analysis depends on the weight of silver taken, and twice draws curves to show this. I assert, on the contrary, that the errors, which average only 1 part in 40,000, are purely accidental, and that they follow no law. This can be proved by proving that the ratios obtained depend on any other quantities selected by accident just as much as they depend on the weights of silver taken. Hinrichs plots the results of the ten determinations, using for abscissas the weights of silver taken, and so obtains tolerable curves. I plotted the same ten observations, using for abscissas not the weights of silver taken but ten numbers selected by *sortes Virgilianæ*, and get curves quite as tolerable as before; and this I did with ten different sets of abscissas, all selected by pure accident. Now, quantities which depend on any one of eleven sets of abscissas, ten of which are selected by accident, are themselves accidental in their variations, and the variations follow no law. So far as the facts are examined, they give no evidence in favor of Hinrichs' proposition; we have seen that theory is equally chary of her support, and we may safely dismiss the suspicion that any source of systematic error can be detected in deducing atomic weights from the means of good experiments.

Within the limits of convenience, it is well to vary the amount of substance taken in analytical determinations. This has been a frequent practice in the finest investigations. But that this practice derives any support from the so-called 'limit method' cannot be conceded.

This criticism, this attempt at a theory, then, removes no obstacles and reveals no threatening pitfalls. If we desire a firmer foundation for our system of atomic weights we must simply enlarge the experimental basis of our knowledge.

If it is only by further experiment that we can make surer of the atomic weight of oxygen, we are to consider what kind of experiments is most desirable. It is chiefly for the sake of eliciting discussion on this point that the subject of this address has been chosen.

Our present value for the ratio between oxygen and hydrogen rests on one single chemical combination, and upon two processes for determination. The first is, the synthesis of water from its components. The second is, the determination of the densities of the gases and of their volumetric ratio. Let us consider these in order.

What synthetic experiments should be repeated? We are met by the fact that a complete synthesis, in which hydrogen and oxygen and water are all three weighed, can be made with errors only about one-fourth as large as the errors in any of the syntheses where only two substances are weighed out of the three concerned. Other things being equal, then, this process is by far the most promising. But, so far it has been carried out adequately by only one experimenter. Conditions were varied somewhat, it is true, but by no means so much as they would be varied if the same person repeated the experiments after an interval of years; by no means so much as if others were to undertake such complete syntheses. Lately, Keiser has devised a process which varies in many particulars from that already executed; it is very desirable that he should make a series of experiments, after adequate study of sources of error and of means of avoiding them. It is also desirable that, if possible, the original process of complete synthesis should be repeated with the little modifications which time is sure to introduce. These two would be enough, as far as synthesis is concerned; unless, indeed, through the invention of another process by a third experimenter, we could have still more. Other syntheses of water than by a *complete* synthesis seem less likely to be of much service, except as a school of experimentation.

What further work is desirable on the ratio of densities and of combining volumes of hydrogen and oxygen? Three constants are involved: the density of oxygen, the density of hydrogen, and the volumetric ratio.

The density of oxygen is known with a probable error of about 1 part in 50,000. It is very probable that no number whatever of further determinations would change this value by 1 part in 10,000. No further work upon this density seems at present desirable, except that whoever determines the density of hydrogen cannot well fail to determine that of oxygen also.

The density of hydrogen demands further experiment. It is possible to make, by some one of three or four slightly different processes, a series of experiments whose average variation shall be less than 1 part in 3000 or 5000, or even 10,000; but different series do not agree sufficiently with each other. We are far from knowing the density of hydrogen so well that more observations might not change our value by 1 part in 2000 or 3000. It is very desirable that further observations should be undertaken by at least two different methods. In one method, hydrogen should be weighed while absorbed in palladium, should be then transferred to a measuring apparatus without the use of stop-cocks, and should be there measured. This process should be repeated with measuring apparatus of varied volumes. In another method, hydrogen should be weighed after Regnault's method, in a counterpoised globe, but with such precautions that leakage through a stop-cock, and contamination with vapor of mercury, should be excluded. The globe should be exhausted till the remaining air is a small fraction of a millionth, should be sealed off from the pump, and should be connected with a condenser at the temperature of liquid air, so as to remove mercurial vapor. After this hydrogen is to be admitted without the use of stop-cocks. The manipulation is not difficult, and the method would confirm the results of the previous method.

The ratio of the combining volumes of hydrogen and oxygen is not known with the degree of confidence which is desirable. The history of the matter is not an uninteresting one. Further continuance of the two series of experiments on which the present value depends would be most unlikely to change it by 1 part in 10,000, for its probable error is 1 part in 40,000. But one of the experimenters has obtained results differing from that finally adopted by as much as 1 part in 220. The other experimenter has entirely discarded the result of one series and replaced it, not by a better series of the same kind but by one of a quite different nature, not carried to its proper completion, and accordingly reduced by the use of the constants of van der Waals' equation. It is desirable that experiments be made to furnish means for a new reduction by measuring the change of volume when 2 volumes of hydrogen and 1 volume of oxygen are mixed, being at the same pressure before and after mixing. This experiment has lately been made by Berthelot, whether with sufficient precision for the purpose is not known at this moment. It is also desirable that the ratio of the combining volumes of oxygen and hydrogen should be measured with the gases contained in vessels of the dimensions of those used for obtaining their densities.

If these syntheses and these studies of ratios of densities and combining volumes should agree as well as it is safe to expect, we should know the atomic weight of oxygen as confidently as we can know it while the value rests on a single chemical process, the combination of the two gases to form water.

But this is not so much as is desirable. We know the atomic ratio between silver and oxygen with considerable confidence, because this rests not on a single chemical process but on eight different chemical processes, which give eight independent results, and because these eight results agree. Is there, then, any chemical process by which the atomic ratio of oxygen and hydrogen can be determined, other than the analysis or synthesis of water? Is there any element whose atomic ratio to oxygen is well known, whose ratio to hydrogen is capable of accurate direct determination?

It is probable that, given an adequate equipment, the direct ratio of hydrogen to chlorine, of hydrogen to sodium, of hydrogen to magnesium, or of hydrogen to aluminum, could be determined with sufficient precision for the purpose, provided that the ratio of chlorine to oxygen, of sodium to oxygen, of magnesium to oxygen, and of aluminum to oxygen are well enough known. This may not now be the case with aluminum or magnesium, but is the case with chlorine and with sodium, whose atomic ratios to oxygen may be fairly assumed to be known within 1 part in 2500. If, now, we can determine the ratio of chlorine to hydrogen, or of sodium to hydrogen, to 1 part in 5000, we could compute, by a new method, the ratio between hydrogen and oxygen. If this should agree with the present value, within some such quantity as 1 part in 2000, we should be as confident of the truth of our value of the atomic weight of oxygen as we can well hope to be.

The difficulties in making a complete synthesis of hydrochloric acid are not small, nor are they all well understood. Some unexpected circumstance may be prohibitive. But there is good reason to hope that 3 or 4 or 5 grams of hydrogen could be weighed, that a nearly equivalent quantity of chlorine could also be weighed, that the two could be combined, and that the product could be weighed. One serious difficulty would be found in attempting to prepare pure chlorine, but the difficulty does not seem insuperable. The manipulation of the corrosive element requires invention, but seems not difficult. For the collection of the hydrochloric acid in a weighable form, there seem to be alternative methods, not very troublesome of execution, unless unforeseen difficulties are encountered. If the ratio between hydrogen and chlorine could be determined to 1 part in 5000 or to 1 part in 10,000, it would be a very interesting addition to our list of known constants, most helpful in establishing confidence in the ratio between oxygen and hydrogen.

So, also, if sodium can be prepared of sufficient purity, or of sufficiently constant impurity, it seems possible to weigh 100 or 200 grams, to act on with water in such a way as to produce a slow evolution of hydrogen, and to determine the weight of this hydrogen by loss. Whether sodium can be obtained sufficiently free from absorbed hydrogen and whether it can be prepared for weighing without attacking the vessels which contain it, are questions which need further experiment. It is probable that a vessel of platinum-iridium alloy could be made which would make success almost certain, but at considerable cost. In this case also, if the ratio between sodium and hydrogen can be determined to 1 part in 5000, or 1 part in 10,000, the result would inspire confidence, or, if it must be, distrust, in our present value for the ratio between oxygen and hydrogen.

These suggestions, necessarily tentative in their nature, are submitted to the American Chemical Society, in the hope of obtaining from those who do me the honor to listen to them or to read them, expressions as to the desirability of making experiment in the lines described, and discussions of the new methods indicated as possible.

CRUISE OF THE ALBATROSS.
III.

Mr. Agassiz's third letter written from the *Albatross* to Hon. George M. Bowers, U. S. Commissioner of Fish and Fisheries, is dated Suva Harbor, Fiji Islands, December 11, 1899, and is as follows:

We left Papeete, November 15th, after coaling and refitting on our return from the Paumotus. During our trip to Suva we made a few soundings from Tahiti to Tonga, striking the northern extension of the deep basin lying to the eastward of Niue; the depths ranged from 2472 to 2882, the bottom being red clay. This would indicate a greater extension westward of the zone over which the manganese-nodule bottom extends.

After leaving Niue we steamed for the deep hole of the Tonga-Kermadec Deep, about 75 miles to the eastward of Tonga-Tabu, and in 4173 fathoms made a haul with the Blake beam-trawl, by far the deepest trawl haul yet made. The gear was carefully inspected and strengthened as far as practicable by Captain Moser, and it was with considerable anxiety that we laid out 5000 fathoms of wire rope for our haul. Fortunately, everything went off successfully and we landed the trawl safely back on deck. To my great surprise we found in the bag a number of large fragments of a silicious sponge belonging probably to the genus *Crateromorpha* which had been obtained by the *Challenger* in the Western Pacific, but in depths less than 500 fathoms. We also brought up quite a large sample of the bottom; it consisted of light-brown volcanic mud mixed with radiolarians.

We decided to trawl at 4173 fathoms rather than wait for a possibly deeper sounding, as the conditions for work were admirable and we did not care to run any risk from a change of weather. After our haul we made a still deeper sounding in the proximity of the 4762-fathom sounding marked on the chart, and found 4540 fathoms with the bottom of the same character as at the place where we trawled. We also took a couple of soundings in the line from Vavau to the southern extremity of the Lau Group in Fiji, but found, as we expected from the soundings given further south, comparatively shoal water, viz., 1381 fathoms. In the channel north of Yangasá, where we crossed the Lau Plateau between Yangasá and Mothe, we found 453 fathoms, with bottom composed of coral sand, pteropod ooze and a few globigerinæ. Between Namuka and Yangasá we obtained 324 fathoms, between Namuka and Marambo 600 fathoms, and between it and Kambara 450 fathoms, and finally about 15 miles west of Kambara we sounded in 990 fathoms. These soundings would indicate a continuous plateau of moderate depths from Wailangolala south upon which the islands of the Lau Group rise.

On our way back to Papeete from the Paumotus we examined the eastern coast of Tahiti, and from Papeete examined the western coast as far as Port Phaeton at Tararao Isthmus. We examined in a general way the Leeward Society Islands: Murea, Huaheine, Raiatea, Tahaa, Bora-Bora, Motu Iti and Maupiti. There are excellent charts of the Society Islands, so that it was comparatively simple to examine the typical points of the group and to gain an idea of their structure as far as it relates to coral reefs. The Society Islands are all volcanic islands edged with shore platforms, some of great width, upon which the barrier or fringing reefs of the islands have grown. The structure of the reefs of the Society Islands is very similar to that of the Fiji reefs round volcanic islands. A comparison, for instance, of the charts of Kandavu, Viti Levu, Mbengha, Nairai, and and of other volcanic islands in the Fijis, with those of the Society group, will at once show their identity. Huge platforms of submarine denudation and erosion characterize both, with fringing and barrier reefs determined by local conditions. Perhaps it is easier to follow the changes which have taken place in the Society Islands; and such islands as Tahaa and Bora-Bora, where we anchored, as well as Maupiti, are admirable examples and epitomes of the structure and mode of formation of the coral reefs of that group.

In Motu Iti and Tetuora the volcanic peaks have disappeared, leaving nothing but a shallow platform upon the outer edges of which sandy coral islets have been thrown up. There is, however, one point in which the barrier reefs of the Society Islands differ from those of Fiji. The barrier reefs in Fiji are generally indicated merely by reef flats, upon which the sea breaks, and an occasional rocky islet or negro-head; only rarely do we find sand keys upon the fringing reefs of the islands of Fiji. In the Society Islands, on the contrary, we find the line of the barrier reef usually well indicated by long lines of narrow islets thrown upon the reef platforms, exactly as they are in the Paumotus. These islands and islets are usually well wooded, and thus give a very peculiar aspect to the barrier reef. In the case of Bora-Bora, Maupiti and Aitutaki, for instance, we have a central volcanic peak of considerable height surrounded by a wide lagoon, the sea edge of which is formed by a fringe of wooded islets and islands forming a more than half-closed ring around the central island which, in Bora-Bora and Maupiti, rise in slopes and nearly vertical walls, the former to a height of nearly 2400 feet, the other about 1100 feet.

The only island of the Cook group which we examined was Aitutaki, as Atiu is composed of elevated limestone, and Rarotonga is volcanic. I hoped we might find that atoll to be in part volcanic and in part composed of elevated coralliferous limestone; we found it to be volcanic, an island with the structure of Bora-Bora on a smaller scale.

We anchored at Niue, an island composed of elevated coralliferous limestone showing three well-marked terraces, the lowest of not more than 5 to 10 feet and in many places disappearing completely, the limestone cliffs rising vertically from the sea well into the second or even the third terraces. The vertical faces of the cliffs are dotted with caverns and deeply indented by small cañons extended at right angles to the face of the shore or forming blunt headlands separating short reaches of coral sand beaches. The second terrace varies in height from 50 to 60 feet, the third from 90 to 100 feet. The second terrace is deeply undercut; and in the higher vertical cliffs extending into the third terrace from the sea, the former positions of the terraces are usually indicated by lines of caverns. There are corals on the sea slopes of the first terrace extending to 10 or 12 fathoms growing much as they are found at Makatea.

From Niue we went to the Tongas, which we found a most interesting group. The elevated tertiary coralliferous limestones take here their greatest development, and are on a scale far beyond that of their development in the Lau Group of the Fijis or the Paumotus. The first island of the Tongas we visited, Eua, is perhaps the most interesting of the islands composed of tertiary elevated coralliferous limestone I have visited. From Dana's account of it, evidently given at second hand, I expected to find an island somewhat like Viti Levu on a very much smaller scale. But as we steamed up to it from the east there could be no mistaking the magnificent face of nearly vertical limestone cliffs forming the whole eastern face of the island, and at points rising to over a thousand feet in height. At all projecting points lines of terraces were plainly marked; at the northern point three could be followed, and at the southern extremity five, with perhaps traces of a sixth.

Upon rounding the southern extremity of the island we could see that the island was composed of two ridges, running north, separated by a deep valley, the western ridge being much lower than the eastern, not rising to a greater height than a little over 500 feet. The western ridge is also composed of limestone, and at the headlands we could trace three terraces. There is a narrow shore-platform along the western face, at many points of which there are blow-holes where the sea throws up spray to a considerable height, but these blow-holes are best seen off Cook Point, the southern extremity of Tonga-Tabu.

As we steamed along the western face of Eua Island, we could see the ridges of the eastern side rising above the crests of the lower ridge, its slopes indicating a valley of considerable size. We anchored at English Roads, opposite the outlet of the drainage of the interior basin where a small river has cut its way through a depression in the shore terrace. On landing we followed the crest of the western ridge for a few miles and could see the whole valley forming the basin of the island lying between the two ridges, at our feet; the slopes leading to the bottom are quite gentle, and the valley dips very gradually northward back of the outlet, on the western shore. Nothing could show more clearly that such an island was not an elevated atoll, but a plateau which has been eroded and denuded for a long period of time by atmospheric and other agencies, and in which a deep basin-shaped valley with gentle slopes has been gouged out—a plateau similar to that of Tonga-Tabu Island and of Vavau, but of greater height and less extent.

To the westward of the Tonga Islands is a line of volcanic islands extending nearly 200 miles from Honga Hapai to Fanualai, some of which have been active very recently. Falcon Island disappeared in 1898 and Lette is still active. This line of volcanoes runs at a distance of from 15 to 20 miles parallel with the trend of the four irregularly shaped plateaus upon which rise the Tonga Islands. They are the summits of a great ridge over 200 miles in length, sloping very gradually to the westward and being somewhat more steep to the eastward, into deeper water, towards the smaller platforms from which rise the volcanic peaks of the group. The plateaus of Tonga-Tabu, Namuka, Hapai, and Vavau, being separated by deep valleys connecting the eastern and western flanks of the ridge. These four plateaus rise abruptly from the 100 fathom line. The extremity of the southern one is occupied by Tonga-Tabu Island. The land behind the cliffs of its southern coast rises to a height of over 250 feet and slopes northward very gradually to form the low land which occupies the north coast of the island, and is, except, at Mount Zion and Cook Hill, not more than from 10 to 20 feet above the level of the sea. At Cook Point (and along the southern coast) three terraces are indicated. The northern coast is deeply indented by shallow bays, full of islands, reef flats, and reef patches, on which corals grow in great profusion. In a distance of nearly 10 miles northward of Nuku-Alofa the plateau is nowhere more than 15 fathoms deep; and a long tongue runs northward, gradually deepening into 20 to 50 fathoms to the 100-fathom line.

The Tonga-Tabu plateau is separated from the Namuka Group Plateau by a funnel-shaped channel with a depth passing rapidly into 300 fathoms from the 100-fathom line. The Namuka Plateau is rectangular. The principal island is Namuka, where we anchored. We found the island to be composed of tertiary elevated coralliferous limestone with a shallow sink, filled with brackish water, occupying the southeastern part of the island. The sink is separated by a high sand beach, about 200 yards wide, from the sea.

Namuka Iki, the island next to Namuka, we found to consist, at its southern extremity, of stratified volcanic material resembling somewhat the so-called soapstone of Fiji. I was told that other islands in this group, near Tonumeia, in the center of the Namuka Plateau, were volcanic. Mango, as we could see it from our anchorage, appeared to be volcanic. So that this part of the Tongas is, like the Lau Group in Fiji, made up of islands in part volcanic and in part composed of elevated coralliferous limestone. The eastern edge of the Namuka Plateau (which we did not visit) is edged with small low islands. We merely steamed past the western islands of the Hapai Group, but close enough to see that Tongua, Kotu, and Fotuhaa, which are respectively 120, 120 and 200 feet high, are composed of elevated limestone. The eastern flank of the Hapai Plateau is edged with long low islands with extensive coral reefs along the reef flats of these islands.

The Hapai Plateau is triangular, with isolated islands rising on the northwestern side from the deep water separating it from the Vavau Plateau. It is separated from the Namuka Plateau by a narrow channel with over 300 fathoms of water.

The northernmost plateau of the broad ridge of the Tonga Islands is the Vavau Plateau. This is elliptical, with a long tongue extending on the eastern face of the ridge toward the northern point of the Hapai Plateau, ending in isolated banks (the Disney and Falcon banks), lying to the northward of the broad channel, with over 400 fathoms separating it from the Hapai Group. The Vavau Group is by far the most picturesque of the Tonga Islands. It consists of the principal island of Vavau, extending across the northern part of the Vavau Plateau. Several parts of the island of Vavau are finely terraced; four terraces are indicated there, and other flat-topped smaller islands show traces of two or three terraces. The northern edge rises to a height of more than 500 feet, and slopes in a general way southward and inland. The southern shore is deeply indented by bays and sounds and flanked by innumerable islands and islets, some of considerable height (150 to 250 feet), which gradually become smaller and smaller as they rise toward the southward and eastward, these islands having been formed from the denudation and erosion of the greater Vavau. They form tongues of land and sea and sounds of all shapes and sizes, showing the traces of the former land connections of the islands and islets and their disintegration on the eastward and southward by the action of the sea. The islands and islets to the southward of the main islands rise from more or less extensive reef flats which stud the whole plateau, and on which corals grow in great profusion (mainly Millepora, Porites, Pavonia, Pocillopora, Fungia, and Astrea), to a depth of 5 to 6 fathoms in the sound. In the Namuka Group they extended in the more open waters to 14 and 16 fathoms.

It is evident that in the Tonga Group, which is a very extensive area of elevation, the recent corals have played no part in the formation of the masses of land and of the plateaus of the Tonga Ridge, and that here again, as in the Society Islands and Cook Islands, both also in areas of elevation, they are a mere thin living shell or crust growing at their characteristic depths upon platforms which in the one case are volcanic, in the other calcareous, the formation of which has been independent of their growth.

We expect to leave for the Ellice, Gilbert, and Marshall islands as soon as we can coal and refit.

A. Agassiz.

*THE OCCURRENCE OF APTOSOCHROMATISM IN PASSERINA CYANEA.**

The following remarks upon the Aptosochromatism of *Passerina cyanea*, although of insufficient importance to establish the phenomenon of color change without moult as a constant occurrence in the species, are conclusive enough, I am convinced, to prove the possibility of such a change, and are merely offered as such for what they may be worth.

Individual error and dogmatism have greatly retarded honest effort in this most important branch of ornithological science. It is a singular fact that certain individuals have conceived the idea that a feather once having passed its premature condition is utterly disconnected with the vital system of the bird, and such individuals cling to this belief with a tenacity wonderful to behold. They do not tell us, by the way, how it is that certain species of birds lacking external sebaceous glands manage to present as bright plumage as their allies so provided. Doubtless they may attribute the presence of oily matters upon the surface of the feathers of those species in which these glands are wanting to osmotic action; but admitting this, why not admit Aptosochromatism?

In his article on alleged changes of color in feathers (Bull. Am. Museum Nat. Hist. 1896), Dr. Allen compares a feather to a green leaf, which when once formed, cannot extend its growth to repair any injuries which may arise from insects, etc. This simile might well be carried yet farther and to better advantage. When the later summer or early fall approaches, certain leaves undergo a complete change in color, resulting in the beautiful colors of our September and October woods. The history of the underlying phenomena of autumnal coloration in leaves is very obscure, yet no one doubts the occurrence of the change for an instant. So it is with Aptosochromatism—the individual feathers undergo in many cases complete color changes, and although the underlying processes of these changes may be obscure, the fact of their presence is to my mind undeniable.

At the present time Aptosochromatism has not progressed far enough to encourage one to take up in detail the systematic occurrence of the color change in our species of native birds. It seems evident that for the present, attention should rather be devoted to endeavoring to demonstrate its fundamental principles, without which no science is firm, plainly evident as may be its happening.

Passerina cyanea, apart from its seasonal fall moult by which the plumage acquired in the spring is changed for the duller garb of the fall, doubtless exhibts two forms of Dichromatism, a term whose proper place, I hope, is now recognized as the fundamental term for the complex phenomena of double coloration. As I shall direct my attention toward proving that Aptosochromatism is concurrent in the species, and Ptosochromatism in the present paper will play an inconspicuous part. Both are compre-

* Read before the Nuttall Ornithological Club of Cambridge, Mass., June 5, 1899, with exhibition of the bird worked upon.

hensive terms, by the way, coined by Dr. Coues. The latter term may be defined for convenience, as the occurrence of Dichromatism depending entirely upon the loss of old feathers which are replaced by others of a different color. Both processes subserve the same general purpose and result in a seasonal change of color, in the present example, from that of the fall to the nuptial of the spring. The Ptosochromatic change of the spring will not further be considered here—let it suffice to say that beyond doubt some indigo birds change color in the spring by completely, or nearly so, shedding their feathers. The change not due to such feather loss is what interests us at the present, and will necessarily be presented far from exhaustively. My remarks are based chiefly upon observations conducted during the fall, winter, and early spring of 1898–99, upon a captive male bird. In view of the color of the plumage of my bird, at the time I took possession of it, it must have been in the adult condition, and as such birds are commonly captured while in the adult state, the difficulty in adapting my bird to his captive condition and the heavy feather loss undoubtedly resulting from this may consequently, be explained. I secured it October 13th, while it was nearing the completion of its fall moult, which by October 28th was finished. From that date every cast-off feather was carefully collected and labelled. In order to be sure of obtaining all, a fender was placed about the cage and the room carefully swept at frequent intervals. In addition to this I made many examinations of the bird and secured such specimen feathers in a fresh state as I wished for microscopic examination.

Briefly, the bird was fed mostly upon millet and canary seed, appeared healthy, bathed regularly, and during bright days sang frequently. On March 26th, however, he died after an illness of three days, before which he was as lively as ever. Examination showed constipation to be the probable cause of his untimely death. The color change had progressed excellently however, and but little additional information could have been gained had he lived, excepting the period of time occupied by the entire change. Data is present in sufficient quantity, nevertheless, to enable me to state the time occupied by the change in certain portions of the plumage.

The appearance of my bird as regards color, October 28th, was as follows: Feathers of the head and breast slightly tinged with cobalt, the chief color of the feathers being dull rusty. The breast thus was somewhat mottled in appearance. Back rusty, the concealed centers bluish. Primaries and rectrices blackish with blue edges. Secondaries and coverts broadly edged with rust color. Lower abdomen buffy, ventral area whitish.

From October 28th till January 28th I observed no marked color change, but from February until the bird's death, it was very noticeable. A curious and undoubtedly unnormal process intervened however, and in order to understand this comprehensively I will tabulate the feather loss beginning with the first feather shed after October 28th, when it will be recollected that the bird had completed its moult.

From February 11th to February 28th an average of 50 contours was lost daily. By March 5th the loss had abruptly ceased, and until his death on March 29th the bird lost but one or two feathers daily. The loss of down feathers was very small, not exceeding twenty specimens—a fact of possible importance to be dwelt upon later on. The total summary of the contour feathers lost, carefully estimated at 1350 feathers, appeared to comprise about three-fifths of my bird's entire plumage. They were shed from all parts of the plumage, and in view of the heavy loss I was quite prepared to ultimately conclude that any color change resulting in my bird would ensue from extensive feather loss. I was thus quite unprepared for what eventually followed. Microscopically, the cast-off feathers were broken, abraded and apparently in the worst condition. The barbules were broken or wanting, the barbs in many places worn down, and the rhachis of the larger feathers was split. This is also of importance as will directly be seen. To many observers my bird by March 5th would have been pronounced to be completely moulting. Immature feathers were in prominence especially upon the head and were scattered all about the remaining feathers of the plumage, which, as has been before remarked, amounted to about two-fifths of the entire plumage. The color of a discarded feather, compared with a freshly plucked one from the body, showed in most cases a decided contrast. Not only were the blue portions dull but their superstructures were gone in many cases, the feathers then being dull brownish. A probable, and, as I am convinced, the truthful source of my bird's extensive loss is found indirectly in the temperament of the bird. From the very first it was fretful and timid, fluttering wildly when uncovered in the morning or when the cage was cleaned out. Even an approach in his direction while hanging in the room caused a wild fluttering. Upon such occasions many feathers would be shed, and those remaining were more or less injured. Thus when such a vital process as Aptosochromatism begins to work, these decrepit feathers necessarily would have to be renewed in order to take part in the general plan. The head upon which many pin feathers appeared, naturally received a considerable share of the injury as regards its feathers, and the tail was in a very bad state.

It will be noticed in the table how gradually the loss began, due doubtless to the gradual approach of activity towards color change in the feathers. It must be admitted that this explanation is purely hypothetical, but such a hypothesis, although not of fundamental importance, ofttimes prepares the way for a clearer understanding of the problem under consideration. The small loss of down feathers points in two ways to the truth of this assumption. Firstly, being more or less under the contour feathers they received less of the wear caused to the others, and secondly, having no color change in themselves, their part in the color-changing process was inconspicuous. It is not probable that the bird could have swallowed many down feathers without it being observed in the excrement.

As I frequently examined the bird closely I noticed at once that the developing feathers which were supplying the places of the cast-off ones, far from appearing to change the color of the bird to blue, were actually coming true to the colors in which they were shed, *i. e.*, in the colors of the fall plumage. To be positive I collected and examined extensively and in every case verified this most interesting principle. It will be recollected that in my observations upon the Aptosochromatism of *Chrysotis Levaillanti* (see *Osprey*, III., No. 8, April, '99), similar results were noticed. In later dates a few parti-changed feathers were found in the embryonic condition, but these may be readily accounted for in two ways, for in no cases were fully changed feathers so detected. (1) Where a partially changed feather had been pulled out or shed and was being renewed, and (2) where a feather had begun to change before it was matured (this being noticed in my parrot investigation). Many of the contradictory and confusing remarks of dealers in birds may perhaps be explained by these most important observations, and it may readily be true that more than a few instances of so-called color changes depending upon spring moults in cage birds, may be due to extensive feather losses precedent to an Aptosochromatic change.

It seems unnecessary to dwell upon the fact that no vital process can readily take place in a greatly injured organic structure, and the renewal of my bird's feathers concurrent with the approach of the macroscopic activity of the color change is, I think, an incident of no little value.

The first appearances of a color change were noticed in some of the old feathers of the crown during the first week of February. Here a brightening of the blue area of the feather was noticed but no perceptible change of color at the tips where the russet was. From this date till the death of the bird a slow but constant change occurred, chiefly noticeable on the rump, throat, and breast. The first indication of the approach of the change externally was the brightening of the blue portion of the feather, beginning evenly on each vane from the bottom. When the band of tawny was reached, it appeared slowly to be absorbed until but faint tips of this color could be seen upon the ends of the larger barbs. In no cases were the barbs or barbules broken off sufficiently to account for the change. A loss of one-third of the length of the feathers in many cases would have been the result, and close observation did not sustain this in the least. I was enabled to notice the change in certain breast feathers, which was much more rapid than that of the parrot before referred to. Yet in the latter case the change which gradually causes the yellow plumage is a slow one of life duration, and but few feathers are involved at a time. That of *Passerina cyanea* is one of comparatively short duration and involves the greater part of the entire plumage.

Upon his death the bird presented the following appearance as regards color. An irregular area of brilliant cobalt blue extended from the throat to the belly down the center of the breast, the feathers upon each side graduating gradually to the sides, where but little change had occurred. Head partially changed in parts, inter-scapulars not perceptibly changed at all (a place where many pin feathers formed). Back altered slightly, rump and scapulars $\frac{2}{3}$ changed to bright greenish blue, the long russet tips almost entirely changed in some feathers, wings and tail unaltered with the exception of the secondaries and coverts, which had slightly changed on the edges. Throat slightly blackish, lower ventral region as with the rump. Assuming, as we safely may, that the first of February marked the beginning of the macroscopic change, we may attribute the total length of time occupied in the change of some of the breast feathers, from the fall to the spring colors, to a period of about fifty days, which for some of the feathers is an over-estimate.

It is not a little curious that the feathers should act so independently and especially so when it is considered that each feather comes true in color.

While skins of birds may serve highly important purposes, it appears essential that for good results in investigations upon color change, one should operate rather upon live birds in confinement. It is quite absurd to suppose that a single generation in confinement would so alter the natural laws of the organism as to obscure Aptosochromatism or Ptosochromatism, if one process or the other be a natural tendency. It is objectively certain that the phenomenon of Aptosochromatism occurs widely, but whether of individual or specific occurrence is not yet clearly shown. While my bird threw out no hint whatever as to the constant occurrence of the color change, it did prove that the 'impossibility' is possible.* It is certain that the heavy feather loss of my bird but indirectly helped the change; 1st, we have seen that many feathers changed which were not renewed by moult; 2d, we saw that those feathers which were renewed by direct gain and loss were colored similarly to those which preceded them, but that later on they changed Aptosochromatically, and 3d, no purely blue, *i. e.*, changed feathers, were found in an embryonic condition at any time, although frequent careful examinations of the bird were made.

Although it is of no positive certainty whether, in the new feathers, the vascular connection with the body was severed, it was found that their complete form was attained in most cases a week or more before a change set in; and in those unshed feathers carried over from the fall, it is quite reasonable to suppose that all connections with the body of the bird were as normal as in other feathers of a similar age. Before the change of color had begun, in December or January, in specimens examined carefully under the microscope, I could detect no presence of carrier pigment cells and found the calamus of each feather to be in the expected dried up condition. The change would thus seem to be confined to activity in the feathers alone.

* Dr. Chadbourne has informed me, since the above was written, that of three confined male indigo birds observed by him, two changed color ptosochromatically and the third 'without any feather loss to speak of,' *i. e.*, aptosochromatically; and still later on, I was delighted to learn during a conversation with Mr. C. J. Maynard that he too had followed a male *Passerina* through its entire spring change of color. The bird involved, belonged to a friend of Mr. Maynard, who informed him that the bird had changed its colors during the season just passed without moulting its feathers. Determined to follow out the change exactly, Mr. Maynard examined the bird frequently the next season, throughout the entire time occupied by the change, and perfectly satisfied himself that it was totally unassisted by a moult or any considerable loss of feathers.

In a brief summary of the principal points already discussed in connection with my bird we may conclude (1) that Aptosochromatism in my *Passerina cyanea* occurred beyond doubt, (2) that although present with severe feather loss it does not follow that the gain of color was directly responsible to it, as proved by careful examination of the newly acquired feathers, and (3) that although the feather loss was objectively independent of the Aptosochromatic change, it might subjectively be so, inasmuch as old and imperfect feathers were renewed for active and healthy ones, in which such a color change subsequently occurred.

The results quoted of Dr. Chadbourne and Mr. Maynard appear to me to be conclusive in themselves and require no further comment. Microscopically, the color change was not of as much prominence as might have been expected at first thought, but it will be recollected that blue and violet colored feathers depend, in a large measure, for their effects, upon involved objective superstructures, which act in combination with some underlying pigment or pigments. These pigments produce chemical objective effects, due to the absorption of all light rays not depending upon the characteristic color of the pigments.

Chemically and microscopically, the feathers of my *Passerina cyanea* appeared to contain two pigments, one, a diffused non-granular tawny colored stain, the other, a granular blackish substance. The yellowish stain was confined to the transparent sheath of the barbs and to the barbules, while the granular matter varied in placement with the color of the feathers.

An unchanged, *i. e.*, fall-colored feather, examined in a fresh state, exhibited the following appearance under the microscope. The rhachis appeared, centrally, to be cellular in construction with an enveloping sheath thickly supplied with the black pigment matter, the granules arranged in an order suggestive of a streaming movement toward the tip of the feather. At the junction with each barb a small portion of the main system curved upward into the central portion of that member. Proximally this column ended in the modification of the rachis into barbs. The center of each barb of the colored parts of the feathers contained a prismatic column, resembling to my eye, a number of bodies set together so as to resemble the nodes and internodes of a bamboo cane. At the distal end of each barb these bodies tapered, and in many cases the extreme joints were separated from the main column. About the blue portions of the feathers, these columns were massed thickly with black matter, the portions giving the rusty effects being much less plentifully supplied, and surrounding this central column a transparent envelope of the yellowish stain was present. The barbules of the non-blue area were the color of this sheath but became well supplied with the dark pigment when the blue-producing area was met with, completely obscuring the presence of the stain. The tips of the prismatic columns showed a pale brownish orange color, but gradually as the microscope slide was passed across the stage the color became deeper until when one-half of the length of the barbs had passed before the objective, it appeared deep black.

The blue area of such a feather gave a good reaction for Zoomelanin (black), for by boiling the feather in KOH, 0.5% and then heating with chlorine, the dark matter was completely broken up, and the feather appeared colored as with the rusty-colored tip which was apparently unaltered by the test.

When compared to a feather wholly changed to blue by the Aptosochromatic process, a valuable suggestion is at once thrown out, as to the nature of the change of color. In a microscopic examination of such a feather it is noticed that the lower parts of the central barb colums were as in the bicolored-fall feathers excepting that the massing of the black appeared to be denser. The upper parts however which were deep orange brown before, varying to lighter tints as the tips of the barbs were approached, now appear thickly massed with the black also, and the yellowish barbules are likewise colored. The streaming movement of the color granules is now especially prominent in an actively changing feather, and it readily appears that the rhachis gives up a part of its matter to the barbs, which in turn supply it to the barbules. A positive change of pigment is manifested macroscopically, for a fall feather held to the light or crushed, remains yellowish in its yellow-colored parts, while a spring feather, appearing entirely blue, so treated, shows darkly, due to the addition of black pigment.

Undoubtedly the blue effects are produced by the prismatic column in coöperation with the dark involved pigment, the sheath enveloping these parts playing its part with the barbules in producing the fall-colored feather. A cross section of the blue-producing barb sustains this view. When placed under the microscope with all light obstructed, but that descending to the stage from above, the sheath became invisible but the central column showed up like phosphorus as a pale glimmering blue which became opalescent with the varying quantities of light admitted. Unsectioned feathers so treated acted quite similarly, but the parts of the column appearing in the tips of the fall feathers, instead of betraying blue, showed gleaming white effects. Under transmitted light, as in ordinary examinations, the effects of the pigments alone were seen.

The massing of the granules of pigment begins evenly upon each vane, from the bottom of each barb and works towards the tips, the barbules being filled, from the tips first, as they are passed. The tips of the distal barbs usually were the last to completely undergo this change.

In both fall and spring feathers, the objective superstructure occupied the same relative position, being confined to the center of the barbs alone for almost their entire lengths.

Dr. Gadow, who has published results of his investigations upon the nature of the blue-producing structures in feathers, concludes that the production of blue is, in a measure, caused by the fine ridges of the prismatic columns, and thinks that the bodies of the columns and the transparent sheaths of the barbs may exert an appreciable influence. He adds in consequence "the production of blue therefore in a feather would be the result of a very complicated process."

As shown in my feathers, however, the blue appeared to be largely independent of the envelope of the barbs, yet this might concentrate light rays or so modify them that the consequent would be helpful. One thing appears certain, that to the presence of quantities of granular black-like matter is due no small share of the ultimate production of blue.

The causes of the differences in the shade of the blue feathers from violet to greenish, according to their position on the bird, appeared to be very slight microscopically, and I could detect no constant characters with the facilities at my disposal.

As to the causes of the activity necessary to produce a color change, we may only infer. As proved by dissection my bird was not undergoing any prominent sexual change, and the theory that the temperature of the atmosphere might be responsible would not be applicable to most cage birds which are kept in warm rooms. There can be no doubt, however, but that the fall change of plumage is one of protective tendency, and it is highly possible that until changed in the spring, the feathers, in a certain sense, are immature. In the case of the double yellow-headed parrot before mentioned, the color change was of a retrograde nature, but in the present example the process is synthetic rather than otherwise.

Numerous theories have been published which endeavor to account for the dichromatic fall change of many birds, but it would be irrelevant to discuss them here. One thing appears certain, that the process is deeply involved in the vital system of the organism. Professor Beddard cites an example noticed by Professor Weber of a chaffinch which was so colored that one-half of the bird was in the male plumage and the other portion in the female. Dissection proved the bird to be a Hermaphrodite, *i. e.*, the side sustaining the male plumage was found to contain a testicle, while the opposite portion of the body possessed an ovary, and Professor Beddard writes that this curious abnormality had been noticed before.

As no vascular connection appeared to be present in the perfect feathers of my bird, the change appears to be one of internal activity in the feathers themselves, and the simile before mentioned, of the autumn leaf, appears to be still more strongly consistent. The change is none the less vital, however, and ceases with the death of the organism. No tests delicate enough were applied to determine if new matter was formed directly in the feather. It appeared probable that none was, but that the striking change depended upon the massing of the dark granular matter from the rhachis to the barbs and their appendages. The absence of definite data upon the chemistry of animal pigments makes remarks in a qualitative direction wholly undesirable.

To conclude our microscopic study, however, we may affirm: (1) that microscopically as well as macroscopically an appreciable Aptosochromatic change took place in the individual feathers of my *Passerina cyanea;* (2) that this change far from being analytical or retrograde was inclined to the nature of constructive synthesis, probably passive in nature; (3) that the change was definite as shown by comparison with the blue areas of unchanged feathers; (4) that it depended chiefly upon the gain of dark pigment in the vicinity of the prismatic column, and (5) that there was an appreciable difference in the amounts of blackish pigment supplied to the barbs and barbules, before and after the change.

F. J. Birtwell.

Albuquerque, New Mexico.

THE SOCIETY FOR PLANT MORPHOLOGY AND PHYSIOLOGY.

The Society for Plant Morphology and Physiology held its third meeting, with the American Society of Naturalists and the Affiliated Scientific Societies, at Yale University, New Haven Conn., December 27th and 28th, with President J. M. Macfarlane in the chair. For the ensuing year the following officers were elected: *President,* D. P. Penhallow; *Vice-Presidents,* Roland Thaxter and Erwin F. Smith; *Secretary,* W. F. Ganong. The following new members were elected: Oakes Ames, J. M. Coulter, Carrie M. Derick, B. M. Duggar, A. W. Evans, M. A. Howe, L. R. Jones, Henry Kraemer, F. E. Lloyd, D. T. MacDougal, Conway MacMillan, G. T. Moore, Adeline F. Schively, Hermann von Schrenk, Julia W. Snow. The business transacted of most general interest was the appointment of a committee, consisting of W. G. Farlow, D. T. MacDougal and H. von Schrenk to consider ways of securing better reviews of current botanical literature. It was voted to communicate the views of the Society upon this subject to the editors of the *Botanisches Centralblatt.* The following papers were presented. The abstracts are furnished by the authors.

Geotropic Experiments: Dr. G. E. Stone, Massachusetts Agricultural College.

This paper dealt with the question at which angle gravity acts most strongly on a geotropically sensitive organism. The results were obtained by the use of grass nodes and in one or two instances the roots of *Vicia faba* were used. Three methods of experimenting touching upon the solution of this problem were described.

The first series give the results of dynamometer experiments in which the power of growth shown by different nodes placed at different angles was illustrated.

The second method consisted of taking the average of a large number of cut plants grown in moist sand and placed at different angles.

The third method showed the results of experiments due to the after effect of stimulation.

The results of all these experiments were similar and may be partly summarized as follows:

The horizontal position is the position of greatest geotropic excitability. This is shown by the increased amount of weight nodes will lift in this position, the amount of growth they display and the after effect reactions.

The relationship existing between nodes at oblique angles and those in a horizontal position is one which is proportional to the cosines of their angles. This also holds good when the nodes were placed at angles below the horizontal position. Young nodes show a definite response to geotropic stimulus when exposed for so short a period as 30 seconds. The latent period is about 30 minutes long.

On the embryo sac of Saururus cernuus: Dr. D. S. Johnson, Johns Hopkins University.

The development of the bract and flower is essentially like that found in the Piperaceæ by Schmitz. In the material studied there were two ovules to each carpel, of which only one, the upper one, matured to a seed. There are two integuments as in most of the Piperaceæ and both grow up to form the micropyle. The primary archesporial cell is single and hypodermal in position. It divides to a definite archesporial cell and an upper tapetal cell. The former then divides to three potential macrospores, of which the lower only becomes functional. This grows and the nucleus divides in the usual way to form a seven nucleate embryo sac. The embryo sac soon widens at the base to become flask-shaped, with the egg apparatus at the upper end of the neck and one endosperm nucleus in the neck and probably a second one in the body of the flask. The antipodals soon become indistinguishable, probably degenerating. Endosperm cells are formed in the neck of the flask before any change can be seen in the egg itself. In the ripe seed the endosperm is found to have swelled laterally using up only the tip of the large nucellus while the lower or body end of the embryo sac is still without endosperm cells or nuclei. The features of the development of *Saururus* thus far studied give no conclusive evidence of its primitive character.

Upon the best way of securing a good review of Current Botanical Literature: Professor W. G. Farlow, Harvard University.

Professor Farlow's address upon this subject appeared in synopsis in the *Botanical Gazette* for January. He pointed out that this is a question distinct from that of a card catalogue, international or other, of literature. None of the existent journals fully meets the needs of botanists for prompt descriptive synoptic reviews of current literature. The *Botanisches Centralblatt* comes the nearest to the needed journal, and if its reviews were more prompt, and, in many cases, of a more descriptive character, and if it did not take up with original articles so much space which ought to be given to reviews, thus forcing many of the latter into Beihefte for which an additional subscription must be paid, it would be much more satisfactory. The discussion following this paper showed that similar opinions are held generally by botanists in this country, and steps were taken to communicate the Society's opinions upon the subject to the editors of the *Centralblatt.*

Fasciation in the Sweet Potato: Mr. Henry S. Conard, University of Pennsylvania. (By invitation.)

The author stated that typical fasciations $\frac{1}{2}$ in. to 3 in. broad are common in the sweet potato. The internal structure of these differs from that of normal stems only in the shape of the cross-section. On poor soil 12% of the stems are abnormal, on good soil 18% ; counting apices only, 20% are abnormal on poor soil, 54% on good soil. Of the abnormal stems $\frac{1}{2}$% to 1% are ring-fasciated. Such stems enlarge gradually from the base, but maintain a round cross-section. They become hollow within, the cavity opening to the air at the growing apex. The apex has a wavy margin; or the tube may be split above, and may give rise to plain fasciation. The tubular portion may be as much as 2 or 3 ft. long by $\frac{1}{2}$ to $\frac{3}{4}$ in. in diameter. The cavity has on its walls acropetally developed leaves, and adventitious roots; the latter become functional when cuttings of the ring-fasciation are planted. The transverse section shows two bundle-systems, an outer normal one, and an inner surrounding the cavity with its normal phloem facing the cavity. The hollow is bounded by epidermis and cortex. Internal phloem (bicollateral structure) is a marked feature of both internal and external bundle-systems of the ring-fasciated stem, as it is of the normal stem. The two bundle-systems of the anomalous specimens are entirely separate, but merge into common ring-shaped apical meristem. Toward the root the cavity tapers to a close, leaving a ring of bundles; these dwindle away one by one, the phloem elements persisting longest. The writer's observations agree essentially with similar ones of de Vries and Nessler; he also considers Masters' 'tubular stem of Sempervivum' and Qualch's 'fasciated sweet-pea' as probable cases of ring-fasciation.

Leaf Scorch of the Sugar Beet: MR. F. C. STEWART, New York Experiment Station.

During August, 1899, some fields of sugar beets in Central New York were severely injured by sudden scorching of the foliage due to excessive transpiration. The foliage, wholly or in part, turned black and died. A majority of the affected plants recovered and made a second growth, but some were killed outright. The dead roots showed internal browning around the circumference and dark colored, raised, somewhat V-shaped areas on the surface. Later in the season the raised surface areas became affected with dry rot and the dead tissue was eaten away by millipedes, leaving shallow cavities resembling scab spots. It has been proved by an inoculation experiment that the internal browning is not caused by parasitic organisms. All affected beets were low in sugar content.

This paper has been published in New York Agricultural Experiment Station Bulletin, No. 162.

Distribution of red color in vegetative parts in the New England flora: MISS F. GRACE SMITH, Smith College. (By invitation.)

The author called attention to the various and more or less conflicting views as to the meaning of the presence of red color in vegetative parts of plants. In order to test these theories, observations were made to determine how many plants in the New England flora show the red color. Careful account was taken of the exact structural part in which the color occurs, and of the relation of the position of the color to external conditions of light, dryness, etc. The results were reduced to percentages and showed that none of the existent theories will explain the distribution of the color in our vegetation. The conclusion is drawn that either the red color must have several different reasons for being, or else it has some significance to which we as yet have no clue. The studies are to be continued.

On the morphology of certain plants from the Devonian of Europe and America: PROFESSOR D. P. PENHALLOW, McGill University.

The author drew attention in particular to two types of plants which had been the subject of investigation for a number of years.

In 1831 Fleming described certain interesting and peculiar fossils from the Devonian of Scotland under the name of *Parka decipiens*, and subsequently Hugh Miller gave them much consideration in his Old Red Sandstone. Since that time they have excited the interest of paleontologists at various times, but always with reference to the eggs or spawn of some animal form of life. In 1891 they were first clearly proved to be of plant origin by Dawson and Penhallow, who, however, were unable to clearly establish their relations to existing types. So far as investigations have proceeded, we can now recognize a sporocarp enclosing both macro- and micro-sporangia, from which may be obtained the corresponding spores with dimensions of 40 and 15 microns respectively. Prothalli in various stages of development have also been obtained. There is presumptive evidence that the sporocarp may have been stalked as in Marsilia, but the character of the contents points more to an affinity with Pilularia. The association of creeping rhizomes strengthens the supposition that they were aquatics of the general habit of growth of Marsilia and Pilularia, while the recently discovered occurrence of leaves of the general type of Marsilia would seem to add to the validity of this hypothesis. Although closely and constantly associated in the same beds, and even on the same slab, the unfortunate separation of members will not permit final conclusions as to the nature of this plant at the present time.

In 1885, the late Sir William Dawson discovered in the Devonian sandstones of Gaspé, the remains of a gigantic alga to which he subsequently gave the name of *Nematophyton.* This genus has since been found to have a very wide distribution, being found in Great Britain, Germany, and various parts of the United States and Canada as far west as Ohio. At present eight species are distinguished, but it is highly probable that with a more complete knowledge of the plant, this number will be greatly reduced, while the number of genera may have to be increased.

They were plants of arborescent habit, attaining a diameter of two feet or more and a height which was undoubtedly great, but which can only be conjectured from the diameter and the fact that the largest specimen so far recovered from the Hamilton Group of New York, although incomplete, had a length of 24 feet. No foliage or fruit has yet been obtained, and our only guide to relationship is through the character of the internal structure. A pseudo-exogenous structure, as in many Laminarieæ, is conspicuous. Isodiametric, radial or irregularly branching openings occur in the various species, and in these areas or in their immediate neighborhood, the larger cellular elements branch more or less freely into small hyphæ which form an intercellular plexus. The principal elements of structure consist of exceedingly long, non-septate, thick-walled, tubular cells which traverse the stem in the direction of the longitudinal axis—though to a minor extent transversely—and interlace freely to form a medulla as in the larger forms of the Laminarieæ. No surface markings of the walls have been observed, but in one species (*N. Ortoni*) the cells show local enlargements closely resembling the trumpet hyphæ of *Macrocystis.*

One of the most instructive features of these plants is to be found in certain structural modifications which they exhibit. In working up material from various sources, it was discovered that many specimens exhibited certain transitional forms from normal structure to what was described many years since by the late Sir William Dawson under the name of *Celluloxylon primævum.* A closer study revealed the fact that this alteration was incident to the crystallization of the infiltrated silica and the operation of decay, whereby the carbon particles of the original cell walls were redistributed upon the surfaces of the crystals in such a manner as to produce the general effect of a coarse cellular structure.

Notes on the morphology and reproduction of Chlorocystis Cohnii: Mr. G. T. Moore, Dartmouth College. (By invitation.)

The structure and development of this unicellular alga growing on Entromorpha was described and several points differing from those previously recorded were referred to. It was shown that the habit of the plant is not that of a universal endophyte but is quite as often merely epiphytic. The character of the chromatophore was found to vary from the 'one-sided' arrangement, considered by Reinhard as typical, to a condition where the cell wall was completely lined by the color body. Two sizes of zoöspores, formed by successive divisions, were described, but no suggestion of conjugation could be observed and it seems probable that nothing of the kind occurs. In the material examined the discharge of zoöspores was found to take place through a circular opening of considerable size instead of through a tubular neck as recorded by European writers on this subject. The paper will be published in full later.

The roots and mycorhizal adaptations of the Monotropaceæ: PROFESSOR D. T. MACDOUGAL, New York Botanical Garden, and PROFESSOR F. E. LLOYD, Teachers College. (By invitation.)

The Monotropaceæ have been under investigation with respect to their mycorhizæ since 1840. Of the genus *Monotropa*, *M. Hypopitys* only has received consideration, and all references made in text-books hitherto have referred to this plant. *Monotropa uniflora* has now been added to the list. In this plant the roots are found to be entirely invested by the mycelium of the fungal symbiont, even over the cap. The latter is 2–4 cells in thickness but arises from a calyptro-dermatogenic layer. The plerome and periblem arise from a common initial tissue and may not be distinguished for some distance back from the apex. The stele and cortex arising therefrom are not distinctly delimited, there being no well marked endodermis. The stele is very irregular in structure. The hyphæ of the fungus gain access to the epidermal cells at about the backward limit of the root-cap, but never enter these. The short haustorial branches which gain entrance enlarge into more or less irregular vesicles, and these come partly to surround more or less the nucleus which, however, does not become hyperchromatic, but maintains its normal condition for a long time. The epidermal cells ultimately become separated from each other by the hyphæ which penetrate between them, but not between the cells of the cortex, or only very rarely. The vesicles sometimes produce spore-like bodies and are believed to be reproductive. A most interesting gradation from the arrangement of the mycorhizas in the nearly related *Pyrolas* is shown. The branching of the root in *M. uniflora* is exogenous, this result not according with that of Kamiensky on *Hypoitys*.

The general statements which may be made concerning all the Montotropaceæ now studied with reference to their mycorhizas are as follows:

1. The shoots are free from chlorophyll, and have no stomata except in the case of *Pterospora*.

2. The customary relations in size of the root and shoot are lost.

3. The stele is much reduced in both the shoot and root, and shows perforated vessels and companion cells only.

4. The fungus sheathing the root encloses the tip completely, at least at certain seasons, and penetrates the epidermal cells in all of the genera examined. Vesicles, sporrangioids or organs of interchange are formed in the epidermal cells. The relation between the fungus and the seed plant is a pure symbiosis and the latter does not act as a fungus trap in accordance with Frank's theory.

5. The root cap is one to many layered, and with the epidermis is derived from a dermato-calyptrogenic layer. The periblem and plerome are not distinguishable in form or content.

The structure and reproduction of Compsopogon: Dr. Roland Thaxter, Harvard University.

The author gave some account of the distribution of *Compsopogon* in Florida, mentioning the localities where it had been found by himself and others, in fresh as well as partly tidal waters. Its general structure was described, attention being called to the fact that the older filaments may possess a cortex of from two to four layers of cells. Details of cell structure and the normal reproduction by aplanospores were illustrated, as well as the formation of small aplanospores developed from sorus-like groups of superficial cells.

On some diseases of New England Coniferæ: Dr. Hermann von Schrenk, Shaw School of Botany. (By invitation.)

The coniferous woods of this region are being destroyed by the mycelia of a number of fungi, chief among which are, *Polyporus tenella, Polyporus Schweinitzii, Polyporus piceinus, Polyporus pinicola, Polyporus sulfureus* and *Agaricus melleus.* The mycelia bring about characteristic changes in the wood either by destroying the lignin and leaving pure cellulose, or by transforming the wood into a brown brittle substance. The changes are caused by enzymes one of which was obtained from *Polyporus tenella*, capable of destroying the substance hadromal, leaving pure cellulose. This enzyme is not diastase. The extent to which decomposition is carried on is apparently determined by decomposition products such as humus compounds, citric and succinic acids and others. These stop the action of the enzyme at a certain point. The enzyme transforms the wood in great quantities; many pounds of pure cellulose are often found in one place. Masses of cellulose and some hadromal were exhibited. The mycelia of these fungi live both as parasites and saprophytes, some entirely in the ground. The sporophores of many excrete manitose in quantity at the time when the spores are ripe. This may aid in the dissemination by attracting bark beetles. Six forms of wood destruction were described, and specimens and photographs of the same were shown.

Vegetative reproduction and multiplication in Erythronium: Mr. Frederick H. Blodgett, New York Experiment Station. (By invitation.)

The presence of underground runners in *Erythronium americanum* has been recognized for some time. The development of the runners, and especially of the bulbs which are formed from their terminal buds was published in 1895. In the present article the author describes the common origin within the bulb of these runners and of the annual bulbs of the mature individuals, as axillary buds between the base of the stem and the inner bulb scale. The development of the first bulb from the seedling is also described. It is characterized by containing the plumule instead of the normal foliage leaf and remains latent for a year. From one bulb, thus developed from a seed, the life cycle is shown to occupy not less than four years, probably six or seven years in most instances. During this interval runners are given off each year, usually three annually, resulting in a bed in five years of from six to nine plants for each seed, or ninety plants if ten seeds of a single fruit should survive all steps of the cycle.

Current problems in Plant Cytology: Professor J. M. Macfarlane. (Presidential Address.)

This address is expected to appear in abstract in Science.

The structure of starch grains: Dr. Henry Kraemer, Philadelphia College of Pharmacy. (By invitation.)

In the different text-books starch grains are represented as having either a light-colored point of growth (nucleus or hilum) with alternate dark and light lamellæ as figured in Sach's works or having a dark point of growth and alternate light and dark lamellæ as illustrated by Strasburger. The appearance of the grain as given by these and other writers is dependent upon the view of the grain by the observer. In focusing upon the top of the successive lamellæ of the grain, one observes the view as given by Strasburger; whereas if one brings the focus to the base of the lamellæ the appearance of the grain as given by Sachs is observed. If we focus upon the top of the various lamellæ of the potato starch grain, we find not only grayish and light colored lamellæ alternating with each other, but we find in the center of the grayish colored zone at the point of growth a much darker area. A layer having the same appearance as this dark area is also observed on the outside of one or more of the grayish lamellæ. The grayish and dark colored layers, just referred to, have a redish appearance, the dark colored layers being slightly bluish also.

Upon treating the starch grains with an aqueous solution of an aniline stain such as safranin, gentian violet, etc., the stain is apparently taken up by the darker lamellæ, *i. e.*, when focusing upon the top of the layers or lamellæ. On the other hand on treating the grains with chromic acid, calcium nitrate, etc., or with water at different temperatures for varying periods of time, the characteristic sphero-crystalloidal structure is brought out in the light lamellæ, *i. e.*, when focusing on top of the layers or lamellæ.

We find further that the layers which do not take up the aniline stains become blue with iodine, whereas the alternating layers are not at all affected apparently by this reagent. It appears that the layers not affected by iodine, but stained by the aniline colors, are rich in colloidal substances but poor in crystalloidal materials. These correspond to the cellulose layers of Nägeli, the farinose layers of von Mohl and the β-amylose layers of Meyer. The layers stained blue by iodine and not stained by the aqueous aniline solutions, are poor in colloidal substances but rich in crystalloidal materials, these corresponding to the granulose layers of Nägeli and von Mohl and to the α-amylose layers of Meyer.

The toxic action of a series of Sodium Salts: DR. RODNEY H. TRUE, Cambridge, Mass. (By invitation.)

From experimental results worked out by Drs. Kahlenberg and True, the latter formulated the results presented under this title.

After studying the toxic action exerted on roots of *Lupinus albus* by a series of acids and by their Na salts, in view of the ionization of these compounds, an analysis of their toxic action has been made into the partial-toxicities due respectively to H ions, anions and ionized molecules. In inorganic acids of the type of HCl, the action of the anions is so slight, relative to that of H ions, as to be thrown into insignificance. In the organic acids where ionization is usually much less advanced, the predominance of the H effect is less marked. In formic, salicylic, ortho-nitrobenzoic and protocatechinic acids, the H ions exceed in effectiveness all other factors. In propionic, butyric, gallic, cinnamic and hippuric acids the action of the unionized molecules predominates over all other factors. In the sodium salts where a greater degree of ionization exists, a greatly diminished toxic action is seen, due chiefly, apparently, to the action of the anions. In carbolic acid, having its hydrogen in the hydroxyl ($-OH$) form as contrasted with the above organic acids in which it exists as carboxyl ($-COOH$) hydrogen, ionization is at a minimum and the toxic action is due solely to unionized molecules.

Further notes on the Embryology of the Rubiaceæ: PROFESSOR F. E. LLOYD, Teachers College. (By invitation.)

The Rubiaceæ reported upon up till now include the *Stellatæ*. The present paper deals with *Diodia virginiana*, *D. teres*, *Richardsonia pilosa* and *Cephalanthus occidentalis*. All are similar morphologically as to the topography of the ovule. They vary, however, in the relative rapidity of development of the basal partition and of the nucelli. *Cephalanthus* possesses the most rapidly developing basal partition with the result that the ovule is rotated so that the funicle is inserted in the top of the ovary and the embryo sac is inverted. All possess an outgrowth of the funicle, resembling a second integument, which in *Richardsonia* and *Diodia* becomes loaded with raphides and is believed to have a nutritive rôle. The 'spongy' funicular appendage in *Cephalanthus* is shown to be the homolog of that in *Diodia* and *Richardsonia*, but the nutritive function is here less probable. The funicle in *Diodia* and *Richardsonia* is surrounded by a collar of peculiar epithelial cells which in *Richardsonia* are the path of the pollen tubes; the latter never travel freely in the ovarian cavity. The archesporium consists of but one cell which gives rise to four megaspores. One of these is the embro-sac mother cell. The embryo-sac is of the elongated type with the usual number of cells. One of the antipodal cells is rather long in *Diodia*, but the three are of equal size in *Richardsonia* and *Cephalanthus*. *Diodia virginiana*, however, has four antipodal cells from the division of the long cell after the small ones are cut off. The embryo possesses a short cylindrical suspensor from which the haustoria characteristic of the *Stellatæ* are absent. There is, however, evidence of a nutritive function. The embryo develops at first very slowly, in contrast with its rapid early development in the *Stellatæ*, a fact which is correlated with the absence of haustoria. The endosperm at first is parietal.

The stimuli that cause the so-called 'peg' or 'heel' on Cucurbita seedlings: DR. J. B. POLLOCK, University of Michigan.

No abstract of this paper is available.

On the prothallus of Taxodium distichum Richard: MR. W. C. COKER, Johns Hopkins University. (By invitation.)

The archesporium consists of a group of cells near the base of the nucellus. One of its central cells enlarges at the expense of those around it and becomes the embryo-sac. The archegonia arise at the upper end in a group and soon come to lie in a depression, which is at first covered over by the wall of the embryo-sac. There are four neck cells, and a ventral canal cell is cut off. Soon after the formation of its cell-walls the endosperm cells become multinucleate by amitotic division.

The pollen sprouts soon after pollination (which in Baltimore takes place about the middle of March) and reaches the embryo-sac before a solid endosperm has been formed. The end in contact with the sac now contains three nuclei, not greatly differing in size, one of which is the body cell nucleus. This increases in size, surrounds itself with a dense mass of cytoplasm, and just before fertilization divides into two male pro-nuclei each with its mass of cytoplasm. Several pollen tubes may push their much enlarged ends into the depression in the embryo-sac. The male and female pro-nuclei come in contact near the upper end of the oösphere and move towards its base. Fusion is complete about the time the base is reached. The young pro-embryo consists of four tiers of four cells each, the upper tier lying free in the archegonium.

A new type of branching in the leafy Hepaticæ: DR. A. W. EVANS, Yale University. (By invitation.)

According to Leitgeb, who made a thorough study of the various kinds of branching exhibited by this group of plants, his so-called 'Endverzweigung' or 'terminal branching' always occurs in the ventral half of one of the lateral segments cut off from the apical cell. In the curious *Mastigobryum integrifolium* Aust. of the Hawaiian Islands, this same kind of branching occurs in both lateral and ventral segments, showing that it is much less restricted than Leitgeb supposed. In this case the ventral branches, apparently from their place of origin, are specialized as flagella.

The geotropism of split stems: DR. E. B. COPELAND, University of West Virginia. (By invitation.)

Numerous experiments show that if a stem be split into two equal halves and then placed in a horizontal position, the lower half is stimulated to grow more rapidly than the upper. As compared with an erect half stem, the upper horizontal half (that with the split surface downward) has its growth depressed, while the lower horizontal half has its growth considerably more accelerated. This is what happens in an uninjured prostrate stem in the execution of a response to the geotropic stimulus, except that the difference in growth between the halves is much greater when they are separated.

It has been held that in the geotropism of stems there must be at least a transverse transmission of the 'sensation,' by which the halves can compare their positions; but in view of the behavior of the isolated half-stems this argument is obviously invalid.

Some variations and correlations in the leaves of trees: MISS HARRIET B. WINSOR, Springfield, Mass., and DR. W. F. GANONG, Smith College.

This paper, offered as an illustration of method, represented the results of an attempt to apply statistical methods to the study of an ecological problem, namely the factors determining the length of petioles and the size and shape of the leaf. The studies are to be continued.

Perennation in the stem of Lycopodium alopecuroides: DR. J. M. MACFARLANE, University of Pennsylvania.

The author pointed out that in this species the branch extremities begin to dip into the ground in autumn by what has been proved to be geotropic growth. This portion becomes colorless, greatly loaded with starch, and bears leaves that become specially modified from those of the normal green type. When the perennating part is fully developed it is a hook-like depression which lies dormant until the succeeding spring. By succeeding apogeotropic growth it again reaches the surface and assumes its usual development.

Of special interest is the fact that the above peculiarity is being gradually acquired, for while a large proportion of plants show it, a few that may grow protected in loose sphagnum or under water only show it to a feeble extent.

The phytoëcology of the Bay of Fundy salt marshes: DR. W. F. GANONG, Smith College.

At the head of the Bay of Fundy occur great salt marshes which bear a remarkably varied vegetation, showing transitions from the usual salt marsh to fresh-water bogs. The reclamation of the marshes for cultivation brings in another element, and all transitions may be found between the salt and the reclaimed marsh. These transitions of conditions afford an unusual opportunity to investigate some phases of the dynamical relationships of plants to their surroundings, and the author has attempted to work out this problem in ecology. The physical conditions of the marshes are discussed, the flora described and the segregation of the vegetation into formations illustrated. The physiological and structural peculiarities of the leading plants of each formation are then described. Finally an attempt is made to formulate the results into a series of principles of general application.

Complications in Citrus hybridization caused by polyembryony: Mr. H. J. Webber, Department of Agriculture.

During the last five years the writer has made about a thousand hybrids of the various species of *Citrus* commonly cultivated, and has had under his care and observation about an equal number made by Mr. W. T. Swingle. Last spring a careful comparison of the foliage characters of these hybrids led to the interesting observation that where two or three seedlings were developed from a single seed, as was frequently the case, they not infrequently showed marked foliage differences. The fact that the common orange and many other species of the genus *Citrus* are commonly polyembryonic is well known. A single seed of the common orange has been known to produce as high as thirteen different seedlings, although it is seldom that more than three of the embryos are capable of development. Strasburger, in his critical study of the polyembryony of this group, found that the embryos, other than that developed from the fecundated egg cell, are derived from certain cells of the nucellus lying near the embryo sac wall which become specialized, grow and divide rapidly, and form a tissue mass which pushes out into the embryo sac and forms an embryo similar to that formed in the normal way from the egg cell. The embryos formed in this way Strasburger called adventive embryos. If we correctly understand the action of fertilization it is clear that in hybridizing fruits of this sort only those embryos developed from the egg cell proper, as a result of the fecundation, would show an indication of the hybridization. The adventive embryos developed directly from the mother tissue we should not expect to show any of the characters of the male parent. This was the conclusion reached by Mr. Swingle and the writer jointly in discussing the matter several years ago, and the development of the hybrids has now shown this to be the case. In several instances of hybrids of *Citrus aurantium*, which has unifoliolate leaves, with *C. trifoliata*, which has trifoliolate leaves, where the former was used as the female parent, two and three seedlings have been produced from the same seed, one of which had trifoliolate leaves and the others strictly unifoliolate leaves exactly like those of the mother parent. In such cases it is evident that the trifoliolate seedling inherits this character from the male parent and that the embryo from which it grew was developed from the egg cell proper. The other seedlings in such cases, having unifoliolate leaves like the mother parent, are doubtless developed from the so-called adventive embryos. The writer has also observed the same phenomenon in the reciprocal hybrids, *Citrus trifoliata* ♀ × *C. aurantium* ♂, and in the hybrids of *Citrus nobilis* ♀ × *C. aurantium* ♂. The observations have been sufficiently extended so that we may be certain of the common occurrence of the phenomenon in citrous hybridization.

In hybridizing citrous fruits to secure improved sorts this fact unfortunately introduces a serious complication. The majority of citrous hybrids, in almost every case resemble the female parent in foliage characters, and it will thus be seen that until they fruit it will be impossible to determine whether they are true hybrids, showing a preponderating influence of the female parent, or simply false hybrids developed from adventive embryos. It is thus probable, or we may say certain that in such work many seedlings will have to be grown and fruited which are from adventive embryos and are not true hybrids. These of course cannot be expected to give rise to valuable new varieties, and growing them will greatly increase the trouble and expense.

W. F. GANONG,
Secretary.

SCIENTIFIC BOOKS.

Insects, their Structure and Life. By GEORGE H. CARPENTER, B.Sc. London, J. M. Dent & Co. 1899. Pp. 404, figs. 183.

There is need of a modern elementary text-book of entomology covering all the important phases of the study of insects. Comstock's Manual in its present form is chiefly devoted to the systematic and ecologic phases, while Packard's new text-book is given up exclusively to the morphological, physiological and developmental phases of insect biology. Mr. Carpenter's book is an attempt to supply the need. Its six chapters treat respectively of the Form of Insects (anatomy and, very slightly, of physiology), the Life-history of Insects (embryonic and post-embryonic development), the Classification of Insects, the Orders of Insects (these two chapters including the classification of insects as far as families, and brief mention of the habits with families as units), Insects and their Surroundings (ecology) and the Pedigree of Insects (phylogeny). These subjects include all the principle phases of the general biologic study of a group of animals, and in this respect the book is wisely planned to meet a real need. For the most part this presentation of the elementary facts of the 'structure and life of insects' will meet with the approval of teachers of entomology. The selection from the mass of material constituting the science of entomology of the little that can be included in an octavo volume of 400 pages, is a matter requiring a large knowledge of insects and a discriminating and clear pedagogic insight. The author (an active naturalist of Dublin) has a good knowledge of entomology, a discriminating perception of the relative importance of facts, and a clear and simple style.

In undertaking to write an elementary general text-book of entomology, the most difficult task is that of the satisfactory treatment of the systematic phase. The enormous number of insect species precludes the use in such a book of classificatory units smaller than families, and indeed renders the adoption of the family unit unsatisfactory. It is this part of the book, the chapter, Orders of Insects, devoted to the systematic consideration of insects, which is the least satisfactory part of it. To treat systematically the whole class of insects, using families as units, in a few more than one hundred octavo pages, and to impart to this treatment any real interest or life, or, one is forced to say, real value, is too nearly impossible to be expected from even the capable author of this book. He adopts a 15-order classification and races through these orders, leaping family barriers three or four to the page. To be sure, certain mechanical assistance, a resorting to small type, is offered to give each family a chance to have its habits told in two lines instead of one, but that hardly betters matters. There is simply no space for what is the absolute minimum of treatment necessary to make such a syllabus or synopsis worth anything more than a list.

It is with relief, therefore, that we leave this distressful attempt to do the impossible, to examine the following interesting and admirable chapter on 'Insects and their Surroundings,' where those general relations of insects to their surroundings, distribution, parasitism, protective resemblances and mimicry, social and communal life and other phases of insect ecology, are presented. Similarly good are the chapters on embryonic and post-embryonic development. Much of the matter of these chapters has never before been given in a small text-book of entomology, and that is the special value of this book. The illustrations are, while mostly good in themselves, often not very apposite to the context. Very few new figures have been made for the book. The excellent blocks (more familiar to American entomologists than they probably are to English students) of the Division of Entomology of the U. S. Dept. of Agriculture have been drawn on heavily for the book's illustration. One hundred and one out of the one hundred and eighty-three figures are from this source.

A brief but good bibliography is appended and there is an index. The work of printers and binders has been tastefully done. Altogether the book is a useful one, and one that can be recommended to beginning students of insects. VERNON L. KELLOGG.

STANFORD UNIVERSITY, CALIF.

The Strength of Materials. By J. A. EWING, Professor of Mechanism and Applied Mechanics in the University of Cambridge. Cambridge, The University Press. 1899. Octavo. Pp. 246.

It will be news to many Americans to learn that instruction in the subject of the strength of materials is now given at the University of Cambridge and that laboratory work in testing is done there. The mathematical theory of elasticity has long received attention at the universities of England and Scotland, as shown by the works of Todhunter and Pearson, of Love, and of Thompson and Tait; this theory and these volumes have, however, added little to the practical knowledge of the properties of materials and have not influenced engineering constructions. At last, after many years of waiting, there comes from Cambridge a book which recognizes the fact that observation and experiment are essentially necessary, and which sets forth the fundamental principles and facts in a manner likely to be of much value to the engineering students and civil engineers of Great Britain.

In its theoretical discussions the book covers about the same ground as that given in American engineering colleges, but there are few numerical exercises and no problems for solution by the student. That such problems are necessary is, however, recognized by the author in his preface which states that the volume is a lecture room treatment of the subject and should be supplemented by laboratory work and computations. The theory is not given isolated from experience, but methods of testing are explained in an interesting manner, and the principal conclusions of the authorities in all countries are noted. Processes of manufacture which influence strength and ductility also receive some attention. The theory of beams, columns and shafts is presented clearly and concisely, and the subject of stresses in trusses and arches is briefly treated. The author has succeeded admirably in putting much sound doctrine and practical information into a limited space. The notation and terminology leans toward that of the mathematical theory of elasticity, but here and there the author breaks away from that bondage and uses the notation of engineering literature. In short this happy wedlock of theory and practice is one upon which the University of Cambridge should be congratulated. No book has appeared in England in recent years which so fully corresponds to the American ideal of a text-book for sound and successful education. M. M.

GENERAL.

PART V. of the 19th Annual Report, and accompanying Atlas, consists of a collection of papers and reports of the U. S. Geological Survey descriptive of the forests of the West, especially of certain of the forest reserves created by Executive Order of February 22, 1896, prominent among which are the Black Hills, Bighorn, Teton, Yellowstone Park, Priest River, Bitterroot and Washington Forest Reserves. Copies may be secured through United States Senators and Representatives, or by application to the Survey.

THE Liverpool School of Tropical Medicine has just issued a memoir, or small book, containing 'Instructions for the Prevention of Malarial Fever,' for the use of residents in malarious places.

BOOKS RECEIVED.

The Ore Deposits of the United States and Canada. JAMES FURMAN KEMP. New York and London, The Scientific Publishing Co. 1900. Pp. xiv + 481.

Annals of the Astronomical Observatory of Harvard College. EDWARD C. PICKERING, Director. *Visual Observations of the Moon and Planets.* WILLIAM H. PICKERING. Vol. XXXII. Part II. Pp. iv + 117–317. Plates viii–xiv. *Miscellaneous Researches.* Vol. XXXIII. Pp. 287. *Observations made at the Blue Hill Meteorological Observatory.* A. LAWRENCE ROTCH. Pp. 131–280. Cambridge, 1900.

Cyclopedia of American Horticulture. L. H. BAILEY assisted by WILHELM MILLER and many expert Cultivators and Botanists. In 4 volumes. New York, The Macmillan Company. 1900. Vol. I. A.–D. Pp. xxii + 509. $5.00.

SCIENTIFIC JOURNALS AND ARTICLES.

American Chemical Journal, January, 1900. 'On the Molecular Rearrangement of *o*-Aminophenylethyl Carbonate to *o*-Oxyphenylurethane,' by J. H. Ransom. 'Diazocaffeine,' by M. Gomberg. 'The Action of Ethyl Iodide on Tartaric Ester and Sodium Ethylate,' by J. E. Bucher. This number also contains a note on 'Improvements in the Manufacture of Sulphuric Acid.'

February, 1900. 'On Some Abnormal Freezing-point Lowerings produced by Chlorides and Bromides of the Alkaline Earths,' by H. C. Jones and V. J. Chambers. 'The Preparation of Pure Tellurium,' by J. F. Norris, H. Fay and D. W. Edgerly. The authors first prepared pure basic nitrate and then prepared the tellurium from this. 'The Reduction of Selenium Dioxide by Sodium Thiosulphate,' by J. F. Norris and H. Fay. 'Action of Picryl Chloride on Pyrocatechin in Presence of Alkalies,' by H. W. Hillyer. 'Camphoric Acid,' by W. A. Noyes. 'On the Rearrangement of Imido-esters,' by H. L. Wheeler. 'The Double Halides of Antimony with Aniline and the Toluidines,' by H. H. Higbee. 'On the Rancidity of Fats,' by I. Nagel. A note on 'The Wax of the Bacillariaceæ and its Relation to Petroleum.' J. ELLIOTT GILPIN.

The American Naturalist for January is a little late in making its appearance, but its contents may excuse the delay. The first article, by Henry Fairfield Osborn, is a most important contribution to the subject of 'Intercentra and Hypapophyses in the Cervical Region of Mosasaurs, Lizards and Sphenodon,' and is well illustrated. Ales Hrdlicka describes in some detail the 'Arrangement and Preservation of Large Collections of Human Bones for Purposes of Investigation,' and A. D. Mead has an article 'On the Correlation between Growth and Food Supply in Starfish,' in which he shows that starfishes of the same age may vary greatly in size. E. H. Eaton discusses 'The Zoology of the Horn Expedition' to Central Australia, and its bearing on the faunal affinities and geologic changes of Australia, and Henry Fairfield Osborn notes 'A Glacial Pot-Hole in the Hudson River Shales near Catskill, N. Y.' John H. Lovell in 'The Visitors of the Caprifoliaceæ,' describes the structural peculiarities of various genera and species of the honeysuckle family and notes the species of insects which he has observed to visit them, supplementing his notes by the observations of others. There is a large number of reviews, particularly of zoological papers.

THE *Journal of the Boston Society of Medical Science* for January opens with an article by Harold C. Ernst on 'Instruction in Bacteriology in the Medical Schools of America and Europe,' giving an analysis of the replies received from ninety-eight institutions to a circular letter of inquiry. The remainder of the number is devoted to abstracts of papers presented at the meeting of the American Public Health Association, Section of Bacteriology and Chemistry, held October 30, 1899.

SOCIETIES AND ACADEMIES.

SCIENCE CLUB OF THE UNIVERSITY OF WISCONSIN.

AT a special meeting of the Science Club of the University of Wisconsin, on the evening of January 24th, Mr. T. C. Chamberlin, of the University of Chicago, addressed the Club on 'Some recent studies of fundamental problems in geology.' Mr. Chamberlin was for five years president of the University of Wisconsin, and a large audience gathered to greet him and to listen to his admirable presentation of an exceedingly difficult subject. By reason of the fact that many of his hearers were not specialists in science, the address was semi-popular, and by special request of the president of the Club, Mr. C. R. Van Hise, it treated particularly of Mr. Chamberlin's well-known studies in this field. These studies have already engaged his attention for a number of years and are not yet completed. Some of the most important conclusions reached by Mr. Chamberlin were given to his audience as he explained 'in confidence to his friends,' as they are not yet in form for publication. The problems discussed—the origin of the solar system, the source of the earth's heat, the earth's physiognomy, its atmosphere, etc., had all been involved in an attempt to frame an adequate working hypothesis to explain the glacial periods.

It was shown that all the hypotheses thus far advanced to explain the glacial periods fail of correspondence with the known facts of geology, particularly the discovery of glacial periods earlier than that of the Quaternary. The kinetic theory of gases applied to the atmospheres of the planets was found to invalidate the La Placian theory of the universe as well as the later theory of meteoric swarms. The atmosphere being the blanket of the earth the explanation of the earth's warm and cold periods was sought in the variation of the amount of carbon dioxide contained, which would materially affect screening or blanketing capacity. Alternate depletion and repletion of the carbon dioxide of the atmosphere might be caused by the variation in the size of land areas and the consequent variation in the carbonation of rocks, and by the separation of carbonates from the littoral portions of the seas. Mr. Chamberlin discussed a theory of the origin of the earth by the slow accretion of solid matter from without, a theory in contrast with that of La Place, in that instead of beginning with an enormously heavy atmosphere, on his theory an atmosphere could not exist until the earth was about one-tenth grown, and would then be extremely attenuated to increase in density with the enlargement of the planet. The exceeding difficulty of securing data for calculation in this field was emphasized, as was the necessity of submitting not one but a number of working hypotheses to the most searching of tests.

Wm. H. Hobbs.

ZOOLOGICAL CLUB, UNIVERSITY OF CHICAGO, MEETINGS OF DECEMBER, 1899.

The session of December 15th was devoted to a paper by Mr. M. F. Guyer on 'Spermatogenesis of Hybrid Pigeons.' "In the spermatogenesis of hybrid pigeons several abnormalities are manifested. These may be classified conveniently under three heads: (1) abnormalities in the structure of the spermatozoa; (2) abnormalities in mitoses; (3) degeneration of the germinal cells. Abnormalities in the spermatozoan structure were present in sterile hybrids, the most noticeable feature being a varicosity or swelling about the middle of the head. In tracing the development of the spermatozoa, this curious modification was found to be due apparently to a lack of development of the head; the nucleus did not elongate completely as in normal spermatogenesis. Abnormalities in mitosis were marked in both fertile and sterile hybrids. Large numbers of multipolar spindles were present. These were usually of the tripolar type. Occasionally two distinct and separate spindles occurred in one cell. The spermatocytes of the first order were the the cells that showed this phenomenon to the greatest extent. In the normal pigeon the chromosomes in the spermatogonia are sixteen in number and in the primary spermatocyte eight. The latter are laid down in rings and each is evidently double. On the spermatogonia of the hybrid there were sixteen chromosomes and in the primary spermatocytes often more than eight. In the latter there may be several of the large double type and a number of smaller rings, or sixteen small ring chromosomes may occur. If sixteen rings were present they were usually located on two separate spindles, eight to each spindle. Another peculiarity in the mitosis was the frequent inequality in the division of the chromosomes, in some instances only about a fourth of a chromosome going to one pole. It is a well known fact that the descendants of hybrids are remarkably variable, hence the possibility that this irregularity in chromatin distribution of the parent germ cell and the variability of the offspring may be connected in some way immediately suggests itself. As for the degeneration of the germ cells, this phenomenon was observed in sterile birds only."

At the meeting of December 20th, Dr. E. S. Riggs, of the Field Columbian Museum, contributed an illustrated lecture, 'The Fossil Mammals of North America.' A large number of lantern slides were exhibited; among them many reproductions in color of the restorations of fossil mammals executed by Mr. Knight.

C. M. Child.

BIOLOGICAL SOCIETY OF WASHINGTON.

THE 317th meeting was held on Saturday, January 27th. William Palmer exhibited a series of specimens of the Christmas Fern, *Polystichum acrostichoides*, showing variations in growth due to varying conditions of environment. H. J. Webber showed a portion of one of the negatively geotropic roots of the mangrove, *Rhizophora mangle*, stating that their function, like that of the 'knees' of the cypress was that of aëration, and illustrating his remarks with photographs.

Thomas A. Williams presented some 'Notes on a New Species of *Lecidea* from Mexico,' stating that it was related to *L. speirea* Nyl. It is peculiar on account of its *Lecanora*-like fruit, the apothecia presenting a white border when young and being borne on slight elevations of the thallus, after the manner of the species of Bæomyces with sub-sessile fruits. In some instances gonidia were found in the apothecia, but their occurrence seemed to be accidental rather than normal. The bearing of these structural peculiarities on the systematic relationship of this and other *Lecideas* was discussed.

Barton W. Evermann made 'Some Observations concerning Species and Subspecies', basing his remarks upon the species of darters found in the waters of Lake Maxinkuckee and a new species found in Aubeenaubee Creek, the principal tributary of the lake, but not in the lake itself. This fish is evidently derived from *Etheostoma iowæ*, which is found in the lake, but differs from it clearly and constantly, and no intergrading forms are known. Should, for some reason the lake species and that from the creek invade each other's habitat and interbreed, the result would be the production of individuals possessing characters common to the two species and apparently placing them in the relation of species and subspecies, although if this supposed case were definitely *known* to have occurred, we should regard the individuals as hybrids and the other forms as still distinct species. The speaker reviewed the chief categories of subspecies, concluding that many trinomials were in use where a careful examination of the facts would show that the supposed subspecies are really species. The paper will appear in SCIENCE.

T. W. STANTON,
Secretary.

NEW YORK ACADEMY OF SCIENCE.
SECTION OF ANTHROPOLOGY AND PSYCHOLOGY.

THE regular meeting of the Section was held on Monday, January 22d. The first paper of the evening, entitled 'Some Phenomena of Indirect Vision,' was presented by Mr. Clark Wissler. Experiments were made by exposing in the indirect field of vision, while the attention of the observer was fully occupied with objects in the direct field, small letters or numerals. The subjects were not conscious of seeing the characters presented in the indirect field, indeed, one of the subjects whose results were reported did not know until several tests had been made that the characters were there at all. In spite of this failure to receive conscious impressions from the letters and figures, two subjects were found who could by association, and afterwards by memory, give in a large number of cases the correct numeral or letter. These subjects made their associations in the form of visualized images. Many of the errors made were similar to those made in normal vision. Thus, *c* was mistaken for *o*, *35* for *55*, etc. It was held that the experiments suggest a relation between normal phenomena and the abnormal as seen in the hysterical eye, and that they point out a way to more complicated experiments in induced automatic movements.

Professor J. McK. Cattell presented a paper on 'The Relations of Time and Space in Vision.' He described experiments on the perception of moving surfaces, which show that a time series may be perceived as a spacial continuum, and explained that the same phenomena held in the ordinary vision of daily life. Although the eyes, head and body are in continual movement, and the images on the retina are constantly shifting, the field of vision appears to be distinct and stationary. Thus if one glances along a row of books, images follow one another on each retinal element in rapid succession, but these successive and rapid changes result in the perception of a space continuum, all the objects being distinct and arranged side by side.

Professor Buchner read a paper on 'Number Forms.' The paper described with the aid of sketches the fixed visualizations experienced since childhood by a woman 35 years of age.

There are three distinct, uncolored tridimensional forms. The first is half fan-like in shape, lying almost entirely to the left of the mental point of regard, and includes the numbers from 1 to 100. The second includes the names of eight days, from Sunday to Sunday. The third has the names of the twelve months from January to December. The paper pointed out the elements which must appear in any theory of the genesis of the phenomena to which this group belongs.

CHARLES H. JUDD,
Secretary.

CURRENT NOTES ON PHYSIOGRAPHY.

WESTERN NEBRASKA.

A REPORT on the geology and water resources of the westernmost twelfth of Nebraska, by N. H. Darton (19th Ann. Rept. U. S. Geol. Survey, pt. IV., 1899, 721–785, numerous maps and illustrations), presents a very clear picture of an interesting region. The inter-stream areas are generally plateau-like uplands of Tertiary strata, retaining something of their initial smoothness of surface over considerable distances. The sand-hill area of mid-western Nebraska extends west into the broad upland between the North Platte and the Niobrara, where some east-flowing streams are lost. The chief valleys, that of the North Platte being the largest, are cut by streams whose courses seem to be consequent on the general easterly slope given to the region when it was uplifted. Numerous branch streams of unsystematic (insequent) arrangement dissect the valley sides, often producing characteristic bad-lands. The insequent dissection has gone so far between North Platte river and Pumpkinseed creek as to reduce an upland to a narrow ridge with numerous lateral spurs. Pine ridge, trending east and west near the northern border, is the strongest relief in the State; it is a cuesta-like upland whose escarpment is carved into bad-lands by its obsequent streams which descend northward to a denuded area of Cretaceous strata that border the southern flank of the Black hills. The present relation of ground water, springs and streams to a structure and form are well set forth in the later pages of the report. The same author contributes a brief account of the Bad Lands of South Dakota and Nebraska to the September number of the *National Geographic Magazine.*

Mention may be made in this connection of an article by W. D. Matthew on the interpretation of the White river Tertiary strata of Nebraska and South Dakota as an æolian instead of as a lacustrine formation (*Amer. Nat.*, xxxiii., 1899, 403–408).

THE MISSISSIPPI AND MISSOURI RIVERS.

THE annual reports of the commissions on our two greatest rivers (Apps. WW and XX., chief of engineers, United States Army, Washington, 1899) contain a large amount of interesting matter, whose discovery would be much facilitated if the reports were edited with more consideration for their readers. Hundreds of pages without adequate tables of contents and with unchanged page headings make the use of the reports difficult. Numerous measured sections of the Mississippi lead to the conclusion that if the banks are properly revetted to prevent erosion, while levees on the adjacent floodplain restrain the spread of high waters, the channel will be deepened and its capacity to discharge floods increased. The Yazoo basin has 310 miles of levees to protect 7100 square miles of surface. Much money has been spent on the levees by local authorities, and yet it is estimated that the volume of the levees must be increased by more than half in order to bring them up to the proper size. $20,000,000 will be needed to complete the entire levee system; over $2,000,000 having been spent in 1899. The heights of floods, their progress down the river, the locations of levees and areas of overflow are shown on various plates and maps. Besides a new edition of the famous eight-sheet map of the lower Mississippi, a four-sheet map of the upper part of the river was issued during the past year on a scale of 1 : 316,800. No relief is indicated except along the borders of the floodplain, but this suffices to suggest that the valley is the work of a larger river than that now flowing in it; not merely because the valley is wider than the river, but because the curvature of the valley is of a larger pattern than the present river seems capable of producing. The narrow post-glacial rock-walled channel just above Keokuk is well shown in relation to the broader valley up and down stream. Five new sheets of the detailed charts, 1 : 20,000, were issued during the year.

The report on the Missouri announces that it is impracticable to attain permanently useful results in controlling the river at the present rate of expenditure; $317,000 having been spent on river corrections during the year. Along with numerous maps representing various engineering works, the report contains a large number of excellent photographs illustrative of different methods of protecting the river banks, from which an excellent idea of the appearance of the river and of the works undertaken upon it can be gained. A series of detailed charts covering the river from its mouth to Kansas City (400 miles) on a scale of five inches to a mile with five-foot contours, have been drawn but not yet published.

GLACIAL LAKE OUTLETS IN MICHIGAN.

THE 'thumb' of Michigan, enclosing the Saginaw bay branch of Lake Huron on the southeast, is of moderate altitude, yet sufficient to have divided two lobes of the ice sheet of the last glacial epoch, which deposited their interlobate moraines along the axis of the thumb. During the retreat of the ice, the depressions evacuated by these lobes were occupied by lakes; the southeastern by Lake Maumee, overflowing through the outlet past Fort Wayne, long ago described by Gilbert; the northwestern by Lake Saginaw, whose outlet was through the Grand river channel, a magnificent ancient river bed, a mile wide, fifty miles long and sometimes cut over 200 feet deep in the drift. Further retreat of the ice uncovered a point on the crest of the thumb of less altitude than the Fort Wayne outlet; then the southeastern lake drained across the thumb to the northwestern lake, the connecting river carving the Ubly channel, which follows the outer base of an interlobate moraine. The channel is twenty miles long, a mile wide, and from 20 to 100 feet deep. At its southeastern end, its level agrees with that of the shore lines of the lake that it drained; its bed is strewn with bars of gravel and sand, indicating a flow from southeast to northwest; its further end opens upon a delta-like body of gravel at the level of Lake Saginaw. Like the ice-border channels near Syracuse, N. Y., discovered by Gilbert, or those of north Germany recently summarized by Keilhack, the Ubly channel is a geographical feature of marvellous significance in connection with the glacial theory; the interpretation of this excellent example being due to Taylor, in whose admirable series of independent studies it constitutes but one of many items (Ice dams of Lakes Maumee, Whittlesey and Warren, *Amer. Geol.*, xxiv., 1899, 6–38, maps).

CHICAGO AND ITS ENVIRONS.

THE first Bulletin of the Geographic Society of Chicago contains an essay on the 'Geography of Chicago and its Environs' by Salisbury and Alden (pp. 64, 30 figs.). A relief plate as frontispiece shows very clearly the smooth floor of the ancient expanded lake rising towards the rolling uplands through which the lake outlet cut its broad and well-defined channel. The text describes the several physiographic areas, with special reference to the successive stages of the falling lake, of which three are recognized (Glenwood, Calumet, Tolleston). The dunes of the ancient beach ridges that curve around the southern end of Lake Michigan, familiar objects to travelers by rail from the east, are mapped and described.

W. M. DAVIS.

CURRENT NOTES ON METEOROLOGY.

COMPENSATION IN WEATHER.

THE question of seasonal forecasts is considered in the Annual Summary for 1899 of *Climate and Crops: Colorado Section.* The temperature and precipitation data for Denver during the past 28 years have been compiled in order to bring out whatever relation successive seasons bear to one another, in the hope of throwing some light upon the so-called theory of compensation in weather. This theory, stated in a few words, is that a season with an excess or defect of temperature or precipitation is followed by compensating conditions in the succeeding season. The records show that the temperature for a season, or a longer period, furnishes no certain index of the conditions to be expected during the coming season. An exceptionally warm spring or summer following an abnormally cold winter is found to be the exception rather than, as is generally believed, the rule. The conditions with respect to precipitation are much more variable than those connected with the temperature. Notably dry or wet seasons are more likely to be followed by nearly normal ones, than by seasons having compensating, or opposite, characteristics.

In *Nature* for January 25th, MacDowall contributes a further note to this discussion. The subject of this inquiry is the sort of relation subsisting between the cold of a given winter and that of the 30 winters preceding. The cold of the winter seasons is measured by the number of frost days from September to May. The results of the study are as follows: (1) The six mildest winters (since 1871) were each preceded by a 30-year group having more than the average of frost days. (2) The six coldest winters were each preceded by a 30-year group having less than the average of frost days. (3) Of fifteen 30-year groups with excessive cold (*i. e.*, over the average), as many as 12 were followed by mild winters, and only 3 by severe winters.

Studies of the sort here referred to are always interesting, but it must be remembered that the results, so far as they go, relate only to a limited area in each case, and that no definite general conclusions can be reached in this matter without much longer and much more accurate series of observations than we now have.

MONTHLY CLIMATE AND CROP BULLETIN.

The *Climate and Crop Bulletin* of the Weather Bureau for January contains a new feature. This is the addition of a diagram indicating the average daily departure from normal temperature for each day during the month at certain selected Weather Bureau stations east of the Rocky Mountains. These stations are St. Paul, Galveston, Boston, Jacksonville, and Cincinnati. These five cities are believed to represent the general temperature conditions prevailing east of the Rocky Mountains as well as any other like number of stations. Simple graphic representations are always welcome additions in discussions of meteorological phenomena, and this new diagram is certain to meet with approval on the part of all who make use of the *Climate and Crop Bulletin.*

R. DeC. Ward.

Harvard University.

THEODORE POESCHE.

On December 27, 1899, died in Washington, D. C., Theodore Poesche, one of that coterie of scholars of whom Professor Henry said, no one has ever asked me a question that some of them could not answer correctly. Poesche was born at Zoeschen, near Merseburg, graduated at the University of Halle, and was driven to England for participating in the revolution of 1848.

Coming shortly after to America, he published with the coöperation of Carl Copp, a little book entitled 'The New Rome,' in which a comparison is drawn between the hereditary enmity between Rome and Carthage on the one hand and between England and America. In 1857 Poesche came to Washington, where during forty years he served as statistician in the Treasury. In this capacity he was sent in 1872 to advise Bismarck about the working of our internal revenue system. In 1878 appeared his masterpiece, 'Die Arier,' in which the origin of the blonde Aryans, of whom Poesche was a splendid example, is found in the Rökitno marshes of White Russia. The book is a protest against the Asiatic origin of the blondes and contributed no little at the time to change the prevailing opinion. In all his work Mrs. Poesche was the amanuensis of her husband and occupied a prominent place in the Washington literary circle.

O. T. M.

SCIENTIFIC NOTES AND NEWS.

At the meeting of the Royal Geological Society on February 16th, Mr. Henry White, Secretary of the United States Embassy, received on behalf of Mr. G. K. Gilbert, the Wollaston Medal.

Lord Rayleigh, Professor Ramsay, Dr. W. Hittorf and M. Moissan have been elected honorary members of the German Chemical Society.

The polling for the election of a member to represent the University of London in Parliament at last accounts had reached: Sir Michael Foster, 903; Dr. Collins, 662; Mr. Busk, 439.

PROFESSOR MAX VON PETTENKOFER, of Munich, eminent for his contributions to hygiene and sanitation, has been elected a Knight of the Prussian Order Pour le Mérite in the Section of Sciences and Arts.

THE following named medical gentlemen have accepted non-resident membership in the Washington Academy of Sciences: H. P. Bowditch, R. H. Fitz, Boston; A. Jacobi, E. G. Janeway, T. Mitchell Prudden, G. S. Huntington, New York; W. W. Keen, Philadelphia; H. A. Kelley, Wm. Osler, Wm. H. Welch, Wm. S. Halsted, Baltimore; Nicholas Senn, Chicago; P. S. Conner, Cincinnati.

DR. J. B. HATCHER, of Princeton University, whose appointment to the curatorship of paleontology we announced last week, will begin his work at Pittsburg on March 1st.

THE Turin Academy of Sciences has awarded the Bressa Prize of 10,000 lire for the best scientific work published during the past four years to Professor Ernst Haeckel, of Jena.

THE Berlin Academy of Sciences has elected to membership Dr. Wilhelm v. Branco, professor of geology and paleontology in the University.

THE Munich Academy has awarded its great gold medal to the explorer, Eugen Wolf.

THE Academy of Sciences of St. Petersberg has elected Professor Fischer of Berlin, and professor Boltzmann of Vienna, as corresponding members.

THE University of Berlin has conferred an honorary degree of doctor of philosophy on Ignaz Stroof, the chemist at Griesheim.

A BUST of Bernhard von Langenbeck, the eminent surgeon, is to be placed in the great hall of the University of Berlin.

DR. HANS BRUNO GEINITZ, a geologist and paleontologist of distinction, died at Dresden on January 28th in his 86th year.

WE regret also to record, on December 9th, the death of Walter Götze, the botanist, while on an expedition to German East Africa.

THE Highland Agricultural Society has contributed £200 in aid of Professor Ewart's experiments on telegony. A gift of £50 has also been promised by Sir John Gilmour.

A COLLECTION of invertebrate fossils from Tennessee has recently been purchased for the Peabody Museum, Yale University. A rearrangement of many of the specimens in the museum is in progress, and some heretofore inaccessible have been placed on exhibition. The exhibits are to be photographed systematically for an illustrated catalogue.

THE collection of Indian relics which was on exhibition at the Boston Museum for many years, has been presented to the Peabody Museum of Harvard by the heirs of David Kimball. The collection comes from the Algonquins, the Sioux, the Seminoles and the Choctaws, and was made by the famous explorers, Lewis and Clark, about the year 1840.

THE trustees of the Western University of Pennsylvania have decided to begin the erection of the new building of the Allegheny Observatory. It will be erected in River View Park and cost $250,000.

THE St. Petersberg Institute of Experimental Medicine has established a laboratory for the study of plague and for the manufacture of plague serum at Cronstadt. The laboratory is surrounded on all sides by water, so that it can be completely isolated.

THE Brooklyn Institute of Arts and Sciences receives $15,000 by the will of Joseph C. Hoagland.

THE President of the Royal College of Physicians has announced that the annual Harveian Oration would be delivered by Dr. T. Clifford Allbutt, regius professor of physics in the University of Cambridge, that Dr. Archibald Garrod has been appointed Bradshaw Lecturer, and Dr. John Sykes, M.O.H. St. Pancras, Milroy Lecturer for the ensuing year (1901).

THE Washington Academy of Sciences announces that the second of the series of meetings for the exposition of 'Photography as an Aid to Research' will be held at Columbian University at 8 p. m., Thursday, February 15th, when the following topics will be presented: 'Photography as an Aid to the Study of Plants,' by F. V. Coville; 'Photography in the Study of Animal Physiology and Pathology,' by Dr. D. S. Lamb, and 'Photography as an Aid in Medicine and Surgery,' by Dr. W. C. Borden, U. S. A. These will be illustrated by lantern slides. At the succeeding meetings, to be announced later, the following topics will be presented: 'Photography in the Study of Animals; in Geographic Research and Survey; Geology, Paleontology, Astronomy, Physics, Physical and Criminal Anthropology, Ethnology, Archæology, Literature and History.'

The School of Pedagogy, New York University, has announced a special course of lectures on Education, to be given on Monday evenings in March, as follows: March 5th, 'Physical and Mental Growth of Children between the Ages of Six and Twelve Years,' Professor Edward R. Shaw; March 12th, 'Education as a Scientific Pursuit,' Professor Edward Franklin Buchner; March 19th, 'A Fundamental Principle of Mental Development,' Professor Charles H. Judd; March 26th, 'Ethics as determining the End of Education,' Professor Samuel Weir.

The Society of German Men of Science and Physicians will meet at Aachen from the 17th to 21st of September of the present year.

The New York Academy of Sciences will hold its annual meeting on Monday evening, February 26th. The program includes reports of officers for past year: Election of officers, honorary members, corresponding members and fellows; followed by the Presidential Address, by President Henry F. Osborn, entitled 'The Geographical and Faunal Relations of North America, Asia, and Europe during the Tertiary Period.'

The third annual meeting of the National Pure Food and Drug Congress will be held in Washington on March 7th and following days. The meeting is regarded as of special importance as it may increase interest in the National Pure Food and Drug Bill now before Congress.

An International Congress of Ethnographical Science will be held at Paris from the 26th of August to the 1st of September of the present year. There will be seven sections as follows: general ethnology, sociology, psychology religions, linguistics, sciences and arts and descriptive ethnology. The president is M. Maurice Block and the general secretary is M. Georges Raynaud, rue Mouffetard 82, Paris.

The fifth annual mid-winter meeting of the Vermont Botanical Club was held at the University of Vermont, January 26th and 27th. The officers of the club were reëlected: President, Ezra Brainerd; vice-president, C. G. Pringle; secretary and treasurer, L. R. Jones.

A bill has been introduced into the Assembly of the State of New York, providing for a biological station with the objects noted in the last issue of this Journal. The management of the institution is under a board of control, consisting of the New York state fish culturist; the president of the board of the commission of fisheries, game and forest of the state of New York; the president of the New York state fish, game and forest league; the chief of the bureau of nature study of the college of agriculture of Cornell University; and the director of the New York state college of forestry, thus making the board of control to consist of five members. The sum of $10,000 annually is appropriated for the expenses of the station.

An account was quoted from the London *Times* in last week's issue of Science of the work done by Italian students in investigating malaria. Dr. Ronald Ross claims that he was done an injustice, as he had anticipated the Italian investigators in following out the life history of the Hæmamœbidæ (the group of parasites of which the human varieties cause malarial fever) in mosquitoes.

A very valuable machine for cutting minerals, called a *petrotome*, invented by Professor William B. Dwight, of Vassar College, has recently been made accessible for general scientific and commercial uses. Dr. A. E. Foot, of Philadelphia, is to have a large collection of minerals at the Paris Exposition and will exhibit a petrotome in action, to illustrate the best scientific method of cutting rocks and precious stones. Half a dozen large transparent sections have been made by Professor Dwight to be sent to Paris with the machine. One of these is a fossil solidified trunk of a tree. It is seven and a-half inches in diameter and is cut so thin throughout as to show perfectly the microscopic structure of the wood. Another specimen is of a group of Rubelite crystals embedded in Lepidolite, and a third is a section of transparent green serpentine five by two and a-half inches in size. A petrotome has lately been secured by the Geological Commission of Brazil and one by Yale University for their scientific work.

IN spite of the prevalence of typhoid fever in Philadelphia the death rate is lower than usual. The Bureau of Health has given out the following figures for the past twelve years:

	Deaths.	Rate per 1000.
1888	20,372	20.04
1889	20,536	19.74
1890	21,730	20.76
1891	23,367	21.85
1892	24,305	22.25
1893	23,655	21.20
1894	22,680	19.90
1895	23,796	20.44
1896	23,892	20.17
1897	22,735	18.72
1898	23,790	19.18
1899	23,796	18.78

BY a recent decree of the Russian Minister of Education the admission of first-year students by the several medical faculties throughout the empire is restricted to a fixed number. The University of Moscow is limited to 250, Kieff to 200, Charkow to 175, Dorpat to 150, Warsaw to 100, Tomsk to 120, and Kasan to 100. The total number of first-year medical students in Russia must therefore not exceed 1095. This number does not include the students of the St. Petersberg Medico-Military Academy, which may admit 250 first-year students.

ACCORDING to the *Publishers' Weekly*, there were last year published in the United States 176 books in the sciences as compared with 143 in 1898. These numbers do not, however, include educational or medical books, or books in the 'useful arts.'

AT a special meeting of the London Chemical Society of London, Professor T. E. Thorp, F.R.S., gave a memorial lecture in honor of Victor Meyer. He said, according to the report in the London *Times*, that as a friend of nearly 30 years' standing, and as one who studied with him under Bunsen, he had acceded to the request of the council to record its appreciation of the remarkable services rendered by Meyer to the science he cultivated with such assiduity and success. After an account of Meyer in his student days at Heidelberg and of his work as one of Bunsen's assistants, the lecturer told how in 1868 he entered Baeyer's laboratory in Berlin, where his success as a private teacher procured him the position of assistant to Fehling at the Stuttgart Polytechnic. There he made one or two important discoveries, but in less than a year he was called, when barely 24 years of age, to succeed Wislicenus at Zürich. His 13 years' stay there constituted the most fruitful and brilliant period of his career, and before its close he had brought himself within the foremost rank of contemporary investigators. Some idea of his power of work and of the stimulus he gave to others might be gleaned from the fact that during that period the Zürich Laboratory gave close on 130 papers and memoirs to chemical literature. It was at Zürich, too, that he devised his various methods of determining vapor densities and carried out some of his work on the dissociation of the halogens. Pyrochemical problems always interested him, and he expressed the belief that a new chemistry with new and undreamt-of discoveries would disclose itself when vessels were obtained capable of bearing temperatures at which meter could no longer exist and oxyhydrogen gas became an uninflammable mixture. In 1882, when continuing a series of University lectures on benzene derivations which had been interrupted by his friend Weith's death, he made what was, perhaps, his most brilliant discovery, that of thiophen, and within about six months of his first observation he was in a position to show by actual preparations that its chemistry was hardly less extensive than that of benzene itself. On the death of Hübner he was called to Göttingen, and in 1888 to Heidelberg, as successor to Bunsen, with the coveted title of Geheimrath and the promise of a new and enlarged laboratory. In conjunction with a number of his pupils he there began the investigation of the conditions determining both the gradual and explosive combustion of gaseous mixtures, and in 1892 with Wachter he announced the existence of the iodoso-compounds, the study of which led to the discovery of the remarkable substances known as the iodonium bases. The formation and electrolysis of ethereal salts of aromatic acids occupied him from 1894 up to the year of his death, which took place at the age of 49 on August 8, 1897. To the literature of chemistry, either alone or in conjunction with his pupils, he contributed over 300 memoirs and papers. As the director of a large chemical laboratory and as a laboratory teacher he worthily followed in the footsteps of Bunsen. He was an admirable lecturer, clear and vigorous, while as a teacher he had a wonderful power of infusing enthusiasm into his students. His literary ability, combined with his faculty of exposition, made him an admirable writer of popular science articles.

UNIVERSITY AND EDUCATIONAL NEWS.

Mrs. Thomas McKean has given $250,000 to the University of Pennsylvania towards the cost of the new Law School building.

Boston University receives $50,000 by the will of O. H. Durrell, of East Cambridge, Mass.

A half million dollars will be distributed by Dr. D. K. Pearsons of Chicago, beginning March 1st, among fourteen colleges throughout the United States. Most of the donations are made on condition that the colleges raise a certain amount, generally $50,000, or an amount equal to the gift, within a given time. The first college to claim its proportion of the $500-000 is Mount Holyoke College, South Hadley. This college receives $50,000, and the gift will be made March 1st. Some of the other colleges to become beneficiaries of Dr. Pearson's philanthropy are Yankton College, South Dakota; Berea College, Berea, Ky.; Colorado College, Colorado Springs, Col., and McKenzie College Lebanon, Ill., which will receive $50,000. Each has received a former gift from Dr. Pearsons. Dr. Pearsons has already given $2,500,-000 to the cause of education.

The Baltimore Association for the Promotion of the University Education of Women is prepared to offer a foreign fellowship of the value of $500 for the year 1900–1901. Preference will be given in the award of this fellowship to women from Maryland, or women who have identified themselves with educational interests in Maryland.

A school of forestry will be established at Yale University under the Sheffield Scientific School. It will occupy the house left to the University by the late Professor Marsh.

The proposed changes in the examinations for the Mathematical Tripos at Cambridge, abolishing the order of Merit and the Senior Wrangler, have been defeated in the Senate by a vote of 152–139.

Plans are being made for the establishment of a school for scientific instruction and practical training in agriculture and horticulture, to be situated at Chappaqua, 33 miles from New York city. The students would attend lectures and do work in the New York Botanical Garden, which is easily accessible.

It is reported in the daily papers that Mr. Alexis E. Frye, superintendent of schools in Cuba, is arranging for a number of Cuban teachers to attend the Harvard summer school.

It is announced that Rear Admiral William Sampson has been offered and has declined the presidency of the Massachusetts Institute of Technology.

Dr. Samuel J. Barnett, professor of physics in Colorado College, has been appointed assistant professor of physics in the Leland Stanford, Jr. University.

Dr. Edward Lewis Stevens, B.A. (La. State University), Ph.D. (New York University), has been appointed president of the newly established Louisiana State Industrial School.

Dr. W. Wien, professor of physics at the University of Giesen, has been called to Würzberg, and Dr. Ludwig Knor of Jena, has been called to the professorship in chemistry in the University of Freiburg, i. B. Dr. Winkler has been made assistant professor of agriculture in the Agricultural Station at Vienna, and Dr. F. R. Kjellmann, professor of botany in the University of Upsala. Dr. Ebermeyer, professor of agriculture and meteorology at Munich, has retired.

*PSYCHOLOGY AND SOCIAL PRACTICE.**

In coming before you I had hoped to deal with the problem of the relation of psychology to the social sciences—and through them to social practice, to life itself. Naturally, in anticipation, I had conceived a systematic exposition of fundamental principles covering the whole ground, and giving every factor its due rating and position. That discussion is not ready to-day. I am loath, however, completely to withdraw from the subject, especially as there happens to be a certain phase of it with which I have been more or less practically occupied within the last few years. I have in mind the relation of Psychology to Education. Since education is primarily a social affair, and since educational science is first of all a social science, we have here a section of the whole field. In some respects there may be an advantage in approaching the more comprehensive question through the medium of one of its special cases. The absence of elaborated and coherent views may be made up for by a background of experience, which shall check the projective power of reflective abstraction, and secure a translation of large words and ideas into specific images. This special territory, moreover, may be such as to afford both sign-posts and broad avenues to the larger

* Address of the President of the American Psychological Association, New Haven meeting, December, 1899.

sphere—the place of psychology among the social sciences. Because I anticipate such an outcome, and because I shall make a survey of the broad field from the special standpoint taken, I make no apology for presenting this discussion to an Association of Psychologists rather than to a gathering of educators.

In dealing with this particular question, it is impossible not to have in mind the brilliant and effective discourses recently published by my predecessor in this chair. I shall accordingly make free to refer to points, and at times to words, in his treatment of the matter. Yet, as perhaps I hardly need say, it is a problem of the most fundamental importance for both psychology and social theory that I wish to discuss, not any particular book or article. Indeed with much of what Dr. Münsterberg says about the uselessness and the danger for the teacher of miscellaneous scraps of child study, of unorganized information regarding the nervous system, and of crude and uninterpreted results of laboratory experiment, I am in full agreement. It is doubtless necessary to protest against a hasty and violent bolting of psychological facts and principles which, of necessity, destroys their scientific form. It is necessary to point out the need of a preliminary working over of psychological material adapting it to the needs of education. But these are minor points. The main point is whether the standpoint of psychological science, as a study of mechanism, is indifferent and opposed to the demands of education with its free interplay of personalities in their vital attitudes and aims.

I.

The school practice of to-day has a definite psychological basis. Teachers are already possessed by specific psychological assumptions which control their theory and their practice. The greatest obstacle to the introduction of certain educational reforms is precisely the permeating persistence of the underlying psychological creed. Traced back to its psychological ultimates, there are two controlling bases of existing methods of instruction. One is the assumption of a fundamental distinction between child psychology and the adult psychology where, in reality, identity reigns; viz.: in the region of the motives and conditions which make for mental power. The other is the assumption of likeness where marked difference is the feature most significant for educational purposes; I mean the specialization of aims and habits in the adult, compared with the absence of specialization in the child, and the connection of undifferentiated status with the full and free growth of the child.

The adult is primarily a person with a certain calling and position in life. These devolve upon him certain specific responsibilities which he has to meet, and call into play certain formed habits. The child is primarily one whose calling is growth. He is concerned with arriving at specific ends and purposes—instead of having a general framework already developed. He is engaged in forming habits rather than in definitely utilizing those already formed. Consequently he is absorbed in getting that all around contact with persons and things, that range of acquaintance with the physical and ideal factors of life, which shall afford the background and material for the specialized aims and pursuits of later life. He is, or should be, busy in the formation of a flexible variety of habits whose sole immediate criterion is their relation to full growth, rather than in acquiring certain skills whose value is measured by their reference to specialized technical accomplishments. This is the radical psychological and biological distinction, I take it, between the child and the adult. It is because of this distinction that children are neither physiologically nor mentally describable as 'little men and women.'

The full recognition of this distinction means of course the selection and arrangement of all school materials and methods for the facilitation of full normal growth, trusting to the result in growth to provide the instrumentalities of later specialized adaptation. If education means the period of prolonged infancy, it means nothing less than this. But look at our school system and ask whether the 3 R's are taught, either as to subject matter or as to method, with reference to growth, to its present demands and opportunities; or as technical acquisitions which are to be needed in the specialized life of the adult. Ask the same questions about geography, grammar and history. The gap between psychological theory and the existing school practice becomes painfully apparent. We readily realize the extent to which the present school system is dominated by carrying over into child life a standpoint and method which are significant in the psychology of the adult.

The narrow scope of the traditional elementary curriculum, the premature and excessive use of logical analytic methods, the assumption of ready-made faculties of observation, memory, attention, etc., which can be brought into play if only the child chooses to do so, the ideal of formal discipline—all these find a large measure of their explanation in neglect of just this psychological distinction between the child and the adult. The hold of these affairs upon the school is so fixed that it is impossible to shake it in any fundamental way, excepting by a thorough appreciation of the actual psychology of the case. This appreciation cannot be confined to the educational leaders and theorists. No individual instructor can be sincere and whole hearted, to say nothing of intelligent, in carrying into effect the needed reforms, save as he genuinely understands the scientific basis and necessity of the change.

But in another direction there is the assumption of a fundamental difference: Namely, as to the conditions which secure intellectual and moral progress and power.* No one seriously questions that, with an adult, power and control are obtained through realization of personal ends and problems, through personal selection of means and materials which are relevant, and through personal adaptation and application of what is thus selected, together with whatever of experimentation and of testing is involved in this effort. Practically every one of these three conditions of increase in power for the adult is denied for the child. For him problems and aims are determined by another mind. For him the material that is relevant and irrelevant is selected in advance by another mind. And, upon the whole, there is such an attempt to teach him a ready-made method for applying his material to the solution of his problems, or the reaching of his ends that the factor of experimentation is reduced to the minimum. With the adult we unquestioningly assume that an attitude of personal inquiry, based upon the possession of a problem which interests and absorbs, is a necessary precondition of mental growth. With the child we assume that the precondition is rather the willing disposition which makes him ready to submit to any problem and material presented from without. Alertness is our ideal in one case; docility in the other. With one, we assume that power of attention develops in dealing with problems which make a personal appeal, and through personal responsibility for determining what is relevant. With the other we provide next to no opportunities for the evolution of problems out of immediate experience, and allow next to no free mental play for selecting, assorting and adapting the ex-

*I owe this point specifically (as well as others more generally) to my friend and colleague, Mrs. Ella Flagg Young.

periences and ideas that make for their solution. How profound a revolution in the position and service of text-book and teacher, and in methods of instruction depending therefrom, would be effected by a sincere recognition of the psychological identity of child and adult in these respects can with difficulty be realized.

Here again it is not enough that the educational commanders should be aware of the correct educational psychology. The rank and file, just because they are persons dealing with persons, must have a sufficient grounding in the psychology of the matter to realize the necessity and the significance of what they are doing. Any reform instituted without such conviction on the part of those who have to carry it into effect would never be undertaken in good faith, nor in the spirit which its ideal inevitably demands; consequently it could lead only to disaster.

At this point, however, the issue defines itself, somewhat more narrowly. It may be true, it is true, we are told, that some should take hold of psychological methods and conclusions, and organize them with reference to the assistance which they may give to the cause of education. But this is not the work of the teacher. It belongs to the general educational theorist—the middleman between the psychologist and the educational practitioner. He should put the matter into such shape that the teacher may take the net results in the form of advice and rules for action; but the teacher who comes in contact with the living personalities must not assume the psychological attitude. If he does he reduces persons to objects, and thereby distorts, or rather destroys, the ethical relationship which is the vital nerve of instruction (*Psychology and Life*, p. 122, and pp. 136–138).

That there is some legitimate division of labor between the general educational theorist and the actual instructor, there is of course no doubt. As a rule, it will not be the one actively employed in instruction who will be most conscious of the psychological basis and equivalents of the educational work, nor most occupied in finding the pedagogical rendering of psychological facts and principles. Of necessity, the stress of interest will be elsewhere. But we have already found reason for questioning the possibility of making the somewhat different direction of interest into a rigid dualism of a legislative class on one side and an obedient subject class on the other. Can the teacher ever receive 'obligatory prescriptions'? Can he receive from another a statement of the means by which he is to reach his ends, and not become hopelessly servile in his attitude? Would not such a result be even worse than the existing mixture of empiricism and inspiration?—just because it would forever fossilize the empirical element and dispel the inspiration which now quickens routine. Can a passive, receptive attitude on the part of the instructor (suggesting the soldier awaiting orders from a commanding general) be avoided, unless the teacher, as a student of psychology, himself sees the reasons and import of the suggestions and rules that are proffered him?

I quote a passage that seems of significance: "Do we not lay a special linking science everywhere else between the theory and practical work? We have engineering between physics and the practical workingmen in the mills; we have a scientific medicine between the natural science and the physician" (p. 138). The sentences suggest in an almost startling way, that the real essence of the problem is found in an *organic* connection between the two extreme terms—between the theorist and the practical worker—through the medium of the linking science. The decisive matter is the extent to which the ideas of the theorist actually project themselves, through the kind offices of the middle man, into the consciousness of the practitioner. It is the participation by the practical man in the theory, through the agency of the linking science, that determines at once the effectiveness of the work done, and the moral freedom and personal development of the one engaged in it. It is because the physician no longer follows rules, which, however rational in themselves, are yet arbitrary to him (because grounded in principles that he does not understand), that his work is becoming liberal, attaining the dignity of a profession, instead of remaining a mixture of empiricism and quackery. It is because, alas, engineering makes only a formal and not a real connection between physics and the practical workingmen in the mills, that our industrial problem is an ethical problem of the most serious kind. The question of the amount of wages the laborer receives, of the purchasing value of this wage, of the hours and conditions of labor, are, after all, secondary. The problem primarily roots in the fact that the mediating science does not connect with his consciousness, but merely with his outward actions. He does not appreciate the significance and bearing of what he does; and he does not perform his work because of sharing in a larger scientific and social consciousness. If he did, he would be free. All other proper accompaniments of wage, and hours, healthful and inspiring conditions would be added unto him, because he would have entered into the ethical kingdom. Shall we seek analogy with the teacher's calling in the workingmen in the mill, or in the scientific physician?

It is quite likely that I shall be reminded that I am overlooking an essential difference. The physician, it will be said, is dealing with a body which either is in itself a pure object, a causal interplay of anatomical elements, or is something which lends itself naturally and without essential loss to treatment from this point of view; while the case is quite different in the material with which the teacher deals. Here is personality, which is destroyed when regarded as an object. But the gap is not so pronounced nor so serious as this objection implies. The physician after all is not dealing with a lifeless body; with a simple anatomical structure, or interplay of mechanical elements. Life functions, active operations, are the reality which confront him. We do not have to go back many centuries in the history of medicine to find a time when the physician attempted to deal with these functions directly and immediately. They were so overpoweringly present, they forced themselves upon him so obviously and so constantly that he had no resource save a mixture of magic and empiricism: magic, so far as he followed methods derived from uncritical analogy, or from purely general speculation on the universe and life; empiricism, so long as he just followed procedures which had been found helpful before in cases which somewhat resembled the present. We have only to trace the intervening history of medicine to appreciate that it is precisely the ability to state function in terms of structure, to reduce life in its active operations to terms of a causal mechanism, which has taken the medical calling out of this dependence upon a vibration between superstition and routine. Progress has come by taking what is really an activity as if it were only an object. It is the capacity to effect this transformation of life activity which measures both the scientific character of the physician's procedure and his practical control, the certainty and efficacy of what he, as a living man, does in relation to some other living man.

It is an old story, however, that we must not content ourselves with analogies. We must find some specific reason in the principles of the teacher's own activities for believing that psychology—the ability to transform a living personality into an objective mechanism for the time being—is not merely an incidental help, but an organic necessity. Upon the whole, the best efforts of teachers at present are partly paralyzed, partly distorted, and partly rendered futile precisely from the fact that they are in such immediate contact with sheer, unanalyzed personality. The relation is such a purely ethical and personal one that the teacher cannot get enough outside the situation to handle it intelligently and effectively. He is in precisely the condition in which the physician was when he had no recourse save to deal with health as entity or force on one side, and disease as opposing agency or invading influence upon the other. The teacher reacts *en bloc*, in a gross wholesale way, to something which he takes in an equally undefined and total way in the child. It is the inability to regard, upon occasion, both himself and the child as just objects working upon each other in specific ways that compels him to resort to purely arbitrary measures, to fall back upon mere routine traditions of school teaching, or to fly to the latest fad of pedagogical theorists—the latest panacea peddled out in school journals or teachers' institutes—just as the old physician relied upon his magic formula.

I repeat, it is the fundamental weakness of our teaching force to-day (putting aside teachers who are actually incompetent by reason either of wrong motives or inadequate preparation), that they react in gross to the child's exhibitions in gross without analyzing them into their detailed and constituent elements. If the child is angry, he is dealt with simply as an angry being; anger is an entity, a force, not a symptom. If a child is inattentive, this again is treated as a mere case of refusal to use the faculty or function of attention, of sheer unwillingness to act. Teachers tell you that a child is careless or inattentive in the same final way in which they would tell you that a piece of paper is white. It is just a fact, and that is all there is of it. Now it is only through some recognition of attention as a mechanism, some awareness of the interplay of sensations, images and motor impulses which constitute it as an objective fact that the teacher can deal effectively with attention as a function. And, of course, the same is true of memory, quick and useful observation, good judgment and all the other practical powers the teacher is attempting to cultivate.

Consideration of the abstract concepts of mechanism and personality is important. Too much preoccupation with them in a general fashion, however, without translation into relevant imagery of actual conditions is likely to give rise to unreal difficulties. The ethical personality does not go to school naked, it takes with it the body as the instrument through which all influences reach it, and through control of which its ideas are both elaborated and expressed. The teacher does not deal with personality at large, but as expressed in intellectual and practical impulses and habits. The ethical personality is not formed—it is forming. The teacher must provide stimuli leading to the equipment of personality with active habits and interests. When we consider the problem of forming habits and interests we find ourselves at once confronted with matters of this sort: What stimuli shall be presented to the sense organs and how? What stable complexes of associations shall be organized? What motor impulses shall be evoked, and to what extent? How shall they be induced in such a way as to bring favorable stimuli under greater control, and to lessen the danger of excitation from undesirable stimuli? In a word, the teacher is dealing with the psychical factors that are concerned with furtherance of certain habits, and the inhibition of others—habits intellectual, habits emotional, habits in overt action.

Moreover, all the instruments and materials with which the teacher deals must be considered as psychical stimuli. Such consideration involves of necessity, a knowledge of their reciprocal reactions—of what goes by the name of causal mechanism. The introduction of certain changes into a net-work of associations, the reinforcement of certain sensori-motor connections, the weakening or displacing of others—this is the psychological rendering of the greater part of the teacher's actual business. It is not that one teacher employs mechanical considerations, and that the other does not, appealing to higher ends; it is that one does not know his mechanism, and consequently acts servilely, superstitiously and blindly, while the other, knowing what he is about, acts freely, clearly and effectively.*

The same thing is true on the side of materials of instruction—the school studies. No amount of exaltation of teleological personality (however true, and however necessary the emphasis), can disguise from us the fact that instruction is an affair of bringing a child into intimate relations with concrete objects, positive facts, definite ideas and specific symbols. The symbols are objective things in arithmetic, reading and writing. The ideas are truths of history and of science. The facts are derived from such specific disciplines as geography and language, botany and astronomy. To suppose that by some influence of pure personality upon pure personality, conjoined with a knowledge of rules formulated by an educational theorist, an effective interplay of this body of physical and ideal objects with the life of the child can be effective, is, I submit, nothing but an appeal to magic, plus dependence upon servile routine. Symbols in reading and writing and number, are both in themselves, and in the way in which they stand for ideas, elements in a mechanism which has to be rendered operative within the child. To bring about this influence in the most helpful and economical way, in the most fruitful and liberating way, is absolutely impossible save as the teacher has some power to transmute symbols and contents into their working psychical equivalents: and save as he also has the power to see what it is in the child, as a psychical mechanism, that affords maximum leverage.

* That some teachers get their psychology by instinct more effectively than others by any amount of reflective study may be unreservedly stated. It is not a question of manufacturing teachers, but of reinforcing and enlightening those who have a right to teach.

Probably I shall now hear that at present the danger is not of dealing with acts and persons in a gross, arbitrary way, but (so far as what is called new education is concerned) in treating the children too much as mechanism, and consequently seeking for all kinds of stimuli to stir and attract—that, in a word, the tendency to reduce instruction to a merely agreeable thing, weakening the child's personality and indulging his mere love of excitement and pleasure, is precisely the result of taking the psycho-mechanical point of view. I welcome the objection for it serves to clear up the precise point. It is through a partial and defective psychology that the teacher, in his reaction from dead routine and arbitrary moral and intellectual discipline, has substituted an appeal to the satisfaction of momentary impulse. It is not because the teacher has a knowledge of the psycho-physical mechanism, but because he has a partial knowledge of it. He has come to consciousness of certain sensations, and certain impulses, and of the ways in which these may be stimulated and directed, but he is in ignorance of the larger mechanism (just as a mechanism), and of the causal relations which subsist between the unknown part and the elements upon which he is playing. What is needed to correct his errors is not to inform him that he gets only misleading from taking the psychical point of view; but to reveal to him the scope and intricate interactions of the mechanism as a whole. Then he will realize that while he is gaining apparent efficacy in some superficial part of the mechanism, he is disarranging, dislocating and disintegrating much more fundamental factors in it. In a word he is operating not as a psychologist, but as a poor psychologist, and the only cure for a partial psychology is a fuller one. He is gaining the momentary attention of the child through an appeal to pleasant color, or exciting tone, or agreeable association, but at the expense of isolating one cog and ratchet in the machinery, and making it operate independently of the rest. In theory, it is as possible to demonstrate this to a teacher, showing how the faulty method reacts unhappily into the personality, as it is to locate the points of wrong construction, and of ineffective transfer of energy in a physical apparatus.

This suggests the admission made by writers in many respects as far apart as Dr. Harris and Dr. Münsterberg—that scientific psychology is of use on the pathological side—where questions of 'physical and mental health' are concerned. But is there anything with which the teacher has concern that is not included in the ideal of physical and mental health? Does health define to us anything less than the teacher's whole end and aim? Where does pathology leave off in the scale and series of vicious aims and defective means? I see no line between the more obvious methods and materials which result in nervous irritation and fatigue; in weakening the power of vision, in establishing spinal curvatures; and others which, in more remote and subtle, but equally real ways, leave the child with, say, a muscular system which is only partially at the service of his ideas, with blocked and inert brain paths between eye and ear, and with a partial and disconnected development of the cerebral paths of visual imagery. What error in instruction is there which could not, with proper psychological theory, be stated in just such terms as these? A wrong method of teaching reading, wrong I mean in the full educational and ethical sense, is also a case of pathological use of the psycho-physical mechanism. A method is ethically defective that, while giving the child a glibness in the mechanical facility of reading, leaves him at the mercy of suggestion and chance environment to decide whether he reads the 'yellow journal,' the trashy novel, or the literture which inspires and makes more valid his whole life. Is it any less certain that this failure on the ethical side is repeated in some lack of adequate growth and connection in the psychical and physiological factors involved? If a knowledge of psychology is important to the teacher in the grosser and more overt cases of mental pathology is it not even more important in these hidden and indirect matters—just because they are less evident and more circuitous in their operation and manifestation?

The argument may be summarized by saying that there is controversy neither as to the ethical character of education, nor as to the abstraction which psychology performs in reducing personality to an object. The teacher is, indeed, a person occupied with other persons. He lives in a social sphere—he is a member and an organ of a social life. His aims are social aims; the development of individuals taking ever more responsible positions in a circle of social activities continually increasing in radius and complexity. Whatever he as a teacher effectively does, he does as a person; and he does with and towards persons. His methods, like his aims, when actively in operation, are practical, are social, are ethical, are anything you please —save merely psychical. In comparison with this, the material and the data, the standpoint and the methods of psychology, are abstract. They transform specific acts and relations of individuals into a flow of processes in consciousness; and these processes can be adequately identified and related only through reference to a biological organism. I do not think there is danger of going too far in asserting the social and teleological nature of the work of the teacher; or in asserting the abstract and partial character of the mechanism into which the psychologist, as a psychologist, transmutes the play of vital values.

Does it follow from this that any attempt on the part of the teacher to perform this abstraction, to see the pupil as a mechanism, to define his own relations and that of the study taught in terms of causal influences acting upon this mechanism, are useless and harmful? On the face of it, I cannot understand the logic which says that because mechanism is mechanism, and because acts, aims, values are vital, therefore a statement in terms of one is alien to the comprehension and proper management of the other. Ends are not compromised when referred to the means necessary to realize them. Values do not cease to be values when they are minutely and accurately measured. Acts are not destroyed when their operative machinery is made manifest. The statement of the disparity of mechanism and actual life, be it never so true, solves no problem. It is no distinction that may be used off-hand to decide the question of the relation of psychology to any form of practice. It is a valuable and necessary distinction; but it is only preliminary. The purport of our discussion has, indeed, led us strongly to suspect any ideal which exists purely at large, out of relation to machinery of execution, and equally a machinery that operates in no particular direction.

The proposition that a description and explanation of stones, iron and mortar, as an absolutely necessary causal nexus of mechanical conditions, makes the results of physical science unavailable for purposes of practical life, would hardly receive attention to-day. Every sky-scraper, every railway bridge is a refutation, compared with which oceans of talk are futile. One would not find it easy to stir up a problem even if he went on to include, in this same mechanical system, the steam derricks that hoist the stones and iron, and the muscles and nerves of architect, mason and steel worker. The simple fact is still too obvious; the more thorough-going and complete the mechanical and causal statement, the more controlled, the more economical is the discovery and realization of human aims. It is not in spite of nor in neglect of, but because of the mechanical statement that human activity has been freed, and made effective in thousands of new practical directions, upon a scale and with a certainty hitherto undreamed of. Our discussion tends to suggest that we entertain a similar question regarding psychology only because we have as yet made so little headway—just because there is so little scientific control of our practice in these directions; that at bottom our difficulty is local and circumstantial, not intrinsic and doctrinal. If our teachers were trained as architects are trained, if our schools were actually managed on a psychological basis as great factories are run on the basis of chemical and physical science; if our psychology were sufficiently organized and coherent to give as adequate a mechanical statement of human nature as physics does of its material, we should never dream of discussing this question.

I cannot pass on from this phase of the discussion without at least incidental remark of the obverse side of the situation. The difficulties of psychological observation and interpretation are great enough in any case. We cannot afford to neglect any possible auxiliary. The great advantage of the psychological laboratory is paid for by certain obvious defects. The completer control of conditions, with resulting greater accuracy of determination, demands an isolation, a ruling out of the usual media of thought and action, which leads to a certain remoteness, and easily to a certain artificiality. When the result of laboratory experiment informs us, for example, that repetition is the chief factor influencing recall, we must bear in mind that the result is obtained with nonsense material—*i. e.*, by excluding the conditions of ordinary memory. The result is pertinent if we state it thus: The more we exclude the usual environmental adaptations of memory the greater importance attaches to sheer repetition. It is dubious (and probably perverse) if we say: Repetition is the prime influence in memory.

Now this illustrates a general principle. Unless our laboratory results are to give us artificialities, mere scientific curiosities, they must be subjected to interpretation by gradual reapproximation to conditions of life. The results may be very accurate, very definitive in form; but the task of reviewing them so as to see their actual import is clearly one of great delicacy and liability to error. The laboratory, in a word, affords no final refuge that enables us to avoid the ordinary scientific difficulties of forming hypotheses, interpreting results, etc. In some sense (from the very accuracy and limitations of its results) it adds to our responsibilities in this direction. Now the school, for psychological purposes, stands in many respects midway between the extreme simplifications of the laboratory and the confused complexities of ordinary life. Its conditions are those of life at large; they are social and practical. But it approaches the laboratory in so far as the ends aimed at are reduced in number, are definite, and thus simplify the conditions; and their psychological phase is uppermost—the formation of habits of attention, observation, memory, etc.—while in ordinary life these are secondary and swallowed up.

If the biological and evolutionary attitude is right in looking at mind as fundamentally an instrument of adaptation, there are certainly advantages in any mode of approach which brings us near to its various adaptations while they are still forming, and under conditions selected with special reference to promoting these adaptations (or faculties). And this is precisely the situation we should have in a properly organized system of education. While the psychological theory would guide and illuminate the practice, acting upon the theory would immediately test it, and thus criticise it, bringing about its revision and growth. In the large and open sense of the words psychology becomes a working hypothesis, instruction is the experimental test and demonstration of the hypothesis; the result is both greater practical control and continued growth in theory.

II.

I must remind myself that my purpose does not conclude with a statement of the auxiliary relation of psychology to education; but that we are concerned with this as a type case of a wider problem—the relation of psychology to social practice in general. So far I have tried to show that it is not in spite of its statement of personal aims and social relations in terms of mechanism that psychology is useful, but because of this transformation and abstraction. Through reduction of ethical relations to presented objects, we are enabled to get outside of the existing situation; to see it objectively, not merely in relation to our traditional habits, vague aspirations and capricious desires. We are able to see clearly the factors which shape it, and therefore to get an idea of how it may be modified. The assumption of an identical relationship of physics and psychology to practical life is justified. Our freedom of action comes through its statement in terms of necessity. By this translation our control is enlarged, our powers are directed, our energy conserved, our aims illuminated.

The school is an especially favorable place in which to study the availability of psychology for social practice, because in the school the formation of a certain type of social personality, with a certain attitude and equipment of working powers, is the express aim. In idea at least no other purpose restricts or compromises the dominance of the single purpose. Such is not the case in business, politics and the professions. All these have upon their surface, taken directly, other ends to serve. In many instances these other aims are of far greater immediate importance; the ethical result is subordinate or even incidental. Yet as it profiteth a man nothing to gain the whole world and lose his own self, so indirectly and ultimately all these other social institutions must be judged by the contribution which they make to the value of human life. Other ends may be immediately uppermost, but these ends must in turn be means; they must subserve the interests of conscious life or else stand condemned.

In other words, the moment we apply an ethical standard to the consideration of social institutions, that moment they stand on exactly the same level as does the school, viz.: as organs for the increase in depth and area of the realized values of life. In both cases the statement of the mechanism, through which the ethical ends are realized, is not only permissible, but absolutely required. It is not merely incidentally, as a grateful addition to its normal task, that psychology serves us. The essential nature of the standpoint which calls it into existence, and of abstraction which it performs, is to put in our possession the method by which values are introduced and effected in life. The statement of personality as an object; of social relations as a mechanism of stimuli and inhibitions, is precisely the statement of ends in terms of the method of their realization.

It is remarkable that men are so blind to the futility of a morality which merely blazons ideals, erects standards, asserts law without finding in them any organic provision for their own realization. For ideals are held up to follow; standards are given to work by; laws are provided to guide action. The sole and only reason for their conscious moral statement is, in a word, that they may influence and direct conduct. If they cannot do this, not merely by accident, but of their own intrinsic nature, they are worse than inert. They are impudent impostors and logical self-contradictions.

When men derive their moral ideas and laws from custom, they also realize them through custom; but when they are in any way divorced from habit and tradition, when they are consciously proclaimed, there must be some substitute for custom as an organ of execution. We must know the method of their operation and know it in detail. Otherwise the more earnestly we insist upon our categorial imperatives, and upon their supreme right of control, the more flagrantly helpless we are as to their actual domination. The fact that conscious, as distinct from customary, morality and psychology have had a historic parallel march, is just the concrete recognition of the necessary equivalence between ends consciously conceived, and interest in the means upon which the ends depend. We have the same reality stated twice over: once as value to be realized, and once as mechanism of realization. So long as custom reigns, as tradition prevails, so long as social values are determined by instinct and habit, there is no conscious question as to the method of their achievement, and hence no need of psychology. Social institutions work of their own inertia, they take the individual up into themselves and carry him along in their own sweep. The individual is dominated by the mass life of his group. Institutions and the customs attaching to them take care of society both as to its ideals and its methods. But when once the values come to consciousness, when once a Socrates insists upon the organic relation of a reflective life and morality, then the means, the machinery by which ethical ideas are projected and manifested, comes to consciousness also. Psychology must needs be born as soon as morality becomes reflective.

Moreover, psychology, as an account of the mechanism of workings of personality, is the only alternative to an arbitrary and class view of society, to an aristocratic view in the sense of restricting the realization of the full worth of life to a section of society. The growth of a psychology that, as applied to history and sociology, tries to state the interactions of groups of men in familiar psychical categories of stimulus and inhibition, is evidence that we are ceasing to take existing social forms as final and unquestioned. The application of psychology to social institutions is the only scientific way of dealing with their ethical values in their present unequal distribution, their haphazard execution and their thwarted development. It marks just the recognition of the principle of sufficient reason in the large matters of social life. It is the recognition that the existing order is determined neither by fate nor by chance, but is based on law and order, on a system of existing stimuli and modes of reaction, through knowledge of which we can modify the practical outcome. There is no logical alternative save either to recognize and search for the mechanism of the interplay of personalities that controls the existing distributions of values, or to accept as final a fixed hierarchy of persons in which the leaders assert, on no basis save their own supposed superior personality, certain ends and laws which the mass of men passively receive and imitate. The effort to apply psychology to social affairs means that the determination of ethical values lies not in any set or class, however superior, but in the workings of the social whole; that the explanation is found in the complex interactions and interrelations which constitute this whole. To save personality in all, we must serve all alike—state the achievements of all in terms of mechanism, that is, of the exercise of reciprocal influence. To affirm personality independent of mechanism is to restrict its full meaning to a few, and to make its expression in the few irregular and arbitrary.

The anomaly in our present social life is obvious enough. With tremendous increase in control of nature, in ability to utilize nature for the indefinite extension and multiplication of commodities for human use and satisfaction, we find the actual realization of ends, the enjoyment of values growing unassured and precarious. At times it seems as if we were caught in a contradiction; the more we multiply means, the less certain and general is the use we are able to make of them. No wonder a Carlyle or a Ruskin puts our whole industrial civilization under a ban, while a Tolstoi proclaims a return to the desert. But the only way to see the situation steadily, and to see it as a whole, is to keep in mind that the entire problem is one of the development of science, and of its application to life. Our control of nature with the accompanying output of material commodities is the necessary result of the growth of physical science—of our ability to state things as interconnected parts of a mechanism. Physical science has for the time being far outrun psychical. We have mastered the physical mechanism sufficiently to turn out possible goods; we have not gained a knowledge of the conditions through which possible values become actual in life, and so are still at the mercy of habit, of haphazard, and hence of force.

Psychology, after all, simply states the mechanism through which conscious value and meaning are introduced into human experience. As it makes its way, and is progressively applied to history and all the social sciences, we can anticipate no other outcome than increasing control in the ethical sphere—the nature and extent of which can be best judged by considering the revolution that has taken place in the control of physical nature through a knowledge of her order. Psychology will never provide ready-made materials and prescriptions for the ethical life, any more than physics dictates off-hand the steam engine and the dynamo. But science, both physical and psychological, makes known the conditions upon which certain results depend, and therefore puts at the disposal of life a method for controlling them. Psychology will never tell us just what to do ethically, nor just how to do it. But it will afford us insight into the conditions which control the formation and execution of aims, and thus enable human effort to expend itself sanely, rationally and with assurance. We are not called upon to be either boasters or sentimentalists regarding the possibilities of our science. It is best, for the most part, that we should stick to our particular jobs of investigation and reflection as they come to us. But we certainly are entitled in this daily work to be sustained by the conviction that we are not working in indifference to or at cross-purposes with the practical strivings of our common humanity. The psychologist, in his most remote and technical occupation with mechanism, is contributing his bit to that ordered knowledge which alone enables mankind to secure a larger and to direct a more equal flow of values in life.

JOHN DEWEY.
UNIVERSITY OF CHICAGO.

THE MARINE BIOLOGICAL LABORATORY.

THE twelfth annual session of the Marine Biological Laboratory at Woods Holl, Mass., which was held during the past summer, was lacking in none of the elements of interest and success which have made former sessions notable, while several new and valuable features were added last year for the first time. In addition to the regular courses of instruction in Zoology, Embryology and Botany, there was given last year, under the direction of Professor Loeb, a course on Comparative Physiology. Such a course can be given advantageously only at the seashore where living animals of all classes may be had in abundance. In the organization of this course the Woods Holl Laboratory has taken a unique and advanced position which cannot fail to yield valuable results not only to research but also to physiological instruction throughout the country. Another notable feature was the course of lectures and demonstrations in Comparative Psychology given by Dr. Thorndike. This course was followed with the keenest interest by a large number of persons at Woods Holl. The general lectures, a volume of which is published annually, were unusually numerous and valuable. The facilities for dredging in deep water and for making extensive collecting trips were never before so good, thanks to the courtesies of the Fish Commission Station. The United States Fish Commission steamer, *Fishhawk* and schooner *Grampus*, were stationed at Woods Holl and they, with the smaller vessels of the Commission and of the Marine Biological Laboratory, formed a fleet of vessels equipped for scientific work such as has rarely assembled in one place before.

The attendance at the Laboratory was gratifyingly large; there were seventy-one investigators and seventy-eight students, representing sixty-nine different schools, colleges and universities. When it is remembered that there were last year three other marine laboratories on our Atlantic coast, offering their facilities freely, or for much less than the fee at the Marine Biological Laboratory, there is all the more reason for satisfaction at the large number in attendance. In the character and variety of the research work done the past season was not excelled by any preceding one, and in some respects it surpassed them all.

All these features show that the Marine Biological Laboratory is to-day, as much as at any time in its past history, the center of biological instruction and investigation in this country. This can still be said in spite of the fact that there are numerous other marine and fresh water stations in this country, which are doing excellent work and are worthy of generous praise and support. However, no other American station has the national and even cosmopolitan character of the Woods Holl Laboratory; no other enjoys the coöperation of so large a number of educational and scientific institutions, no where else is the whole field of biology so fully represented and no other American laboratory is so productive in original work, nor has so large a number of investigators and students.

The Marine Biological Laboratory is a shining illustration of the fact that men and not buildings nor material equipment make an institution great. There is probably no other educational or scientific institution in the world which on so small a financial basis has accomplished so great a work. This work is of such scientific and educational value and the Laboratory stands for so fine an ideal of scientific coöperation that a brief account of its history and work should not be wholly lacking in interest or suggestiveness.

The Laboratory can claim to be a lineal descendant of the first marine laboratory in America, the school established by Louis Agassiz in 1873, on the island of Penikese, in Buzzards Bay. The Penikese Laboratory was abandoned in 1874 at the close of its second session, after having received in buildings, equipment and endowment, more money than has been given to the Marine Biological Laboratory during the twelve years of its history. This step was made necessary on account of the unfortunate location of the laboratory on an isolated island, and above all by the death of the man whose genius had created it and who alone was able to secure the scientific coöperation necessary to its maintenance. After the closure of the Penikese Laboratory an attempt was made to secure the coöperation of educational and scientific institutions in establishing a marine laboratory at Woods Holl, but the support was not forthcoming at that time and the project was abandoned.

In 1880 the Woman's Educational Association of Boston, acting in coöperation with the Boston Society of Natural History, opened a seaside laboratory at Annisquam, Mass., and this continued in operation for six years. In 1886 the supporters of that laboratory addressed a circular letter to many leading biologists in this country asking their coöperation in the work of establishing the laboratory on a broader basis. In March, 1887, a meeting of persons interested in the enterprise was held in Boston, and a committee was appointed "to perfect plans for the organization of a permanent seaside laboratory, to elect trustees and to devise ways and means for collecting the necessary funds.'' In the spring of 1888 about ten thousand dollars had been secured, and accordingly the Marine Biological Laboratory was incorporated and steps were taken to open it that season. After prolonged consideration the trustees decided to locate the laboratory at Woods Holl, Mass., and the whole history of the institution has shown the wisdom of this decision.

The natural advantages of Woods Holl deserve especial emphasis because they have been fundamental to the success of the Laboratory. In a good location a biological laboratory may be highly successful with very little equipment, while in a poor location no amount of money can make up for this defect.

In 1881 Professor Baird determined to locate the marine laboratory of the U. S. Fish Commission at Woods Holl, after having investigated, during the preceding ten years, almost every available point on the Atlantic coast. It is doubtful whether at any other single place on this coast so many valuable and important features can be found. The only other place seriously considered by Professor Baird was Newport, R. I., and this was finally rejected because of the relative impurity of the water of Narragansett Bay. On the other hand the waters of Buzzards Bay and Vineyard Sound are of exceptional purity, there being no large fresh water streams in the vicinity nor cities discharging their filth into the waters. In the immediate vicinity of Woods Holl are numerous harbors and lagoons, with muddy, sandy or rocky bottoms, while the coast is so broken by bays, promontories, straits and islands as to afford the most varied habitats. In addition the tide currents which sweep in through the sound and 'hole' bring in multitudes of floating animals and plants, many of which are tropical forms carried in from the Gulf Stream, which is distant only about one hundred miles. The proximity of the Gulf Stream to this portion of the New England coast gives a laboratory located at this point many of the advantages of a tropical station without any of the accompanying disadvantages. There are also many fresh water ponds and lakes in the vicinity which contain a rich fauna and flora. Add to these things the fact that Woods Holl

FIG. 1. Main Building, Marine Biological Laboratory.

is readily accessible by rail or boat, that the climate in summer is delightful, the bathing excellent, the mainland and islands charming, the sound with its continual procession of ships always varied and interesting, and you have in Woods Holl not only an ideal place for a laboratory, but also an ideal place for summer residence.

Having determined to locate the Laboratory at Woods Holl, the Trustees bought a small piece of land near the Fish Commission Station and erected upon it a plain wooden building, 63 x 28 feet and two stories high. This was equipped with the most necessary apparatus and the Marine Biological Laboratory was first opened July 17, 1888.

From the first it was determined that the Laboratory should not be under the control of any college, university or other institution, but that it should be truly national in character and that it should invite the coöperation of all persons and institutions interested in the advancement of the science of Biology. Accordingly the Laboratory was organized on an independent foundation.

Its government was vested in a Corporation and a Board of Trustees. The Corporation, at first ten in number, now consists of several hundred persons, many of them present or former students and investigators at the Laboratory, who are interested in its welfare and have contributed to its support. The Corporation elects annually six members of the Board of Trustees, passes upon all proposed changes in the Constitution and By-Laws, hears an annual report from the Director and the Treasurer and makes such recommendations concerning the general policy of the Laboratory as it may desire. The Board of Trustees, at first seven in number, now consists of twenty-seven members, some of them business men of recognized ability, but most of them biologists representing prominent educational institutions in almost every part of the United States and Canada. The Board has direct charge of the property and funds of the Laboratory, elects the Director and Assistant Director, and has general supervision of the scientific work.

From the first the institution has been under the directorship of Professor C. O. Whitman, and it is but simple justice to say that the remarkable success which has attended it is due in large measure to the high ideals and the untiring energy and sacrifice of Professor Whitman. For twelve years he has devoted himself to the Laboratory without compensation and with an enthusiasm which has served to inspire many others with his own ideals concerning the Laboratory and to enlist their hearty coöperation.

In his address at the opening of the Laboratory and in subsequent publications, Professor Whitman took the position that there was great need for a laboratory which should represent, (1) the whole of biology; (2) both teaching and research; (3) the widest possible coöperation of educational and scientific institutions. Such a laboratory should not be merely a collecting station, nor a summer school, nor a scientific work shop, nor a congress of biologists, but all of these; an institution combining in itself the functions and features of the best biological institutes of the world, having the coöperation of the biologists of this country, and thus forming "a national center of instruction and research in every department of Biology." The history of the Laboratory has shown that this ambitious project is not only highly desirable, but that it is entirely feasible and has justified the claim of the Director that such an institution is the greatest need of American biology.

"The new laboratory at Woods Holl," said the director in his first report, "is nothing more and I trust nothing less than a first step toward the establishment of an ideal biological station, organized on a basis broad enough to represent all important features of the several types of laboratories hitherto known in Europe and America. * * * An undertaking of such magnitude cannot be a matter of local interest merely, and if it be pushed with energy and wisdom, it cannot fail to receive the support of the universities, colleges and schools of the country." There was little in the early conditions of the laboratory to justify such high hopes. It began with no assured co-operation, no constituency, a bare building, no library, no private rooms for investigators, only a row boat for collecting and with only two instructors, seven investigators and eight students.

season $1000 was given to establish the Glendower Evans Library; $2500 was raised in Boston to establish two scholarships at the laboratory as a memorial to Lucretia Crocker, long a supervisor in the public schools of Boston. During the third season a lecture hall and library room were constructed as an addition to the building and the 'Gifford Homestead,' together with about one-half acre of land adjoining the Fish Commission was purchased, the house being converted into a dining hall; a steam launch was also secured. In the fifth year an additional laboratory of the size of the original building was constructed. In the seventh year a new laboratory was built for botany and a large dining hall was erected, capable of accommodating two hundred people at one

Fig. 2. Main Building, Botanical Laboratory, Lecture Hall and Research Laboratory.

Since that time the growth of the laboratory in material equipment has been encouraging, while its growth in numbers and in the scope and volume of scientific work has been phenomenal. During the second

time. In the ninth year a building containing a large lecture hall and research laboratories was constructed and a two-masted schooner was added to the fleet of collecting boats.

Although this growth in material equipment has been rapid, the needs of the laboratory have grown still more rapidly. The buildings are all of a temporary character and can be used only in summer; at least one substantial, fire-proof building is needed which can be used the year around; the library is inadequate to the needs of such an institution; the facilities for collecting should be enlarged and increased; the Laboratory is entirely dependent upon the Fish Commission Station for wharf privileges and for pumping sea water to its aquaria and, although cordial and mutually helpful relations have always existed between the two stations, additional land, with shore privileges, ought to be secured while it can be had; above all the Laboratory needs increased endowments both for special purposes, such as scholarships, library, publications, etc., and also for general maintenance.

Fig. 3. Fish Commission Buildings, Wharf and Steamer, one of the Marine Biological Laboratory Buildings on the right.

The growth in material equipment, though encouraging, is overshadowed in importance by the growth in the number of persons in attendance at the Laboratory. In 1888 there were nine investigators and eight students representing thirteen different institutions of learning; in 1899 there were seventy one investigators and seventy-eight students representing sixty-nine different institutions. In all during the twelve sessions there have been in attendance five hundred and ten investigators and seven hundred and forty-five students from nearly three hundred different educational and scientific institutions, while among the occasional lecturers and visitors must be numbered almost all the better known biologists of this country and many from foreign lands.

As the outgrowth of a summer school it might have been expected that the laboratory would give instruction in biological subjects, and at its very beginning its founders resolved that it should also give opportunity for original research. The combination of these two functions at the Laboratory has been a peculiarly fortunate one. It has been proved, not only here, but also in many universities and scientific institutions, that research and teaching are of mutual service. A certain amount of teaching is stimulating to the investigator, while the atmosphere of research is indispensable to good teaching.

When the Laboratory was first established instruction was given in Zoology only, since then courses have been added in Botany, Embryology, Physiology and it is understood that Comparative Psychology and Nature Study will form a part of the regular program hereafter. In these courses there is an earnestness and enthusiasm on the part of students and instructors which is highly stimulating. This is due not only to the exceptional character of the students and instructors, but also to the atmosphere of investigation which prevades the place and which is one of the most helpful features to the beginner, as well as to the advanced worker. Instruction includes not only ordinary laboratory work in the subject named, but also a great deal of observation and collection of living organisms in their natural haunts. Collecting trips and excursions form a regular part of the work, and a most important and enjoyable part. Investigators and even visitors at the Laboratory cheerfully contribute to the work of instruction, and so it generally happens that the lectures are given by men who are specialists in the subjects under consideration and who are able to teach with the enthusiasm, accuracy and directness of 'those having authority.' When it is remembered that the persons in attendance at the laboratory are almost without exception teachers, the tremendous influence of the Laboratory on the teaching of Biology in the schools, colleges and universities of this country can be surmised.

FIG. 4. A Collecting Trip ; Launch and Schooner in the Background.

In 1891 a Supply Department was opened at the Laboratory for the purpose of furnishing to schools and scientific institutions various kinds of biological material to be found in the vicinity of Woods Holl. The collectors studied the best methods of preserving material, the habitats and breeding seasons of various animals, etc., with the result that the Supply Department has been not only a great financial assistance to the Laboratory, but that it has still further contributed to the scientific purposes for which the Laboratory was established. At present a skilled collector is employed the year around and material is gathered, not only from the vicinity of Woods Holl, but from far distant points.

But it is in the work of investigation

that the Laboratory has won greatest renown. The eminent scientific standing of the Director and his co-laborers has served to attract investigators from all parts of the land, until the Woods Holl Laboratory is to-day the Mecca of American biologists and is well and favorably known throughout the world. The list of original contributions which have proceeded from the Laboratory during the past twelve years numbers about three hundred; many of these are large monographs, illustrated with numerous colored plates, and some of them represent unique lines of research. For example, the study of 'cell-lineage,' as it has been called, had its origin at the Woods Holl Laboratory and has so far been confined almost entirely to that institution. This work consists in tracing the cleavage cells, into which the developing eggs of all animals divide, through the whole development until they give rise to larval or adult organs, such as the brain, nerves, sense organs, glands, alimentary canal, etc. This is in all cases a difficult task, frequently taking years of the most painstaking labor, but its results have been of fundamental and far reaching importance. Thanks to this work we now know the cell-lineage of about a score of worms and mollusks. This work has shown that from their first appearance certain cleavage cells are destined to give rise to certain organs; it has shown that, in the groups mentioned, cleavage is as constant in its character as are adult features; that in animals so widely separated as flat-worms, annelids and mollusks these early divisions of the egg are almost identical and that many corresponding cleavage cells give rise to homologous organs. Incidentally such work has shown the close genetic relationship of the groups named; it has also set a new pace in embryology. Now that we know the exact cell origin of these layers and organs, it will never again be possible in describing the development of these animals to refer the origin of certain organs to 'germ layers' merely, nor to refer the origin of these layers to certain general regions of the embryo. The importance of this line of work, not only in the study of the groups named, but also to the science of embryology as a whole, is fully recognized both in this country and abroad, and the credit for this service belongs in large part to the Woods Holl Laboratory.

Other work of the greatest importance has been done in the line of what has been called 'physiological morphology.' It would exceed the limits of this article to give even a brief description of papers of this class which have issued from the Laboratory. A few of the more striking lines of work, however, must be mentioned. Much attention has been given to experiments on the regeneration of lost parts in various animals. In hydroids, sea-anemones and worms these parts are sometimes reproduced in a normal manner, while under different conditions a head may be caused to develop where a tail belongs or *vice versa*. Another line of work has been the grafting together of different parts of animals. One member of the Laboratory succeeded in grafting together in almost every possible manner the pupæ of different moths and butterflies. Some of these afterwards went through the metamorphosis and came out as 'Siamese twins,' 'tandems' with four wings, etc. Another line of work, even more important, is found in 'experimental embryology.' In one famous experiment performed at the Laboratory, the eggs of the sea-urchin were artificially fragmented before they began their development, and in this way twins, triplets, or still more numerous larvæ might be produced from a single egg. If the fragments of the egg were entirely separate, the larvæ which developed were separate and perfect, if they were united, the larvæ were united forming all kinds of double or multiple monsters. Other experiments have shown that certain salt solutions will cause unfertilized eggs to develop for a short time in an irregular way, and only last summer Professor Loeb discovered that he could cause the unfertilized eggs of the sea-urchin to develop into normal larvæ, in short, could produce artificial parthenogenesis in a phylum in which it has never before been known, by treating them with certain salt solutions; this is certainly one of the most remarkable biological discoveries of recent years. The lines of work outlined above, together with many which could not here be mentioned, and which have been actively prosecuted at the Woods Holl Laboratory, have been substantial contributions toward the solution of some of the most fundamental problems of biology.

Each year a course of general lectures on various phases of biological work is given by different members of the Laboratory and by distinguished visitors. These lectures are usually brief accounts of important investigations, presented in a popular form. A volume of these lectures is published annually and the contents of the volumes form a brief index to the multifarious activities of the Laboratory in research. These volumes are not only important contributions to knowledge, but still more, they are brief and popular presentations of what are often abstruse and difficult subjects, and as such they appeal strongly to investigators, teachers and general readers who have not the time to go more fully into these subjects. As showing the opinion of the outside world with regard to these lectures, the following is quoted from *Natural Science*, December, 1899: "Every biologist who is still young enough to be enthusiastic, looks with eagerness about this time of year for the arrival of the volume of 'Biological Lectures' from the Marine Biological Laboratory, Woods Holl, Mass. * * * One cannot help feeling that the intellectual atmosphere of Woods Holl must be bracing, the lectures are so vigorous. The charm of these lectures may be partly due to the circumstances of their delivery, but it is doubtless mainly due to the fact that each is an expression of personal work and personal interest. One cannot but be grateful to the Laboratory at Woods Holl, which has been the stimulus of the fine series to which this volume is added, *Floreat Woods Holl.*" In addition to the volume of lectures there is also published under the auspices of the Laboratory the *Biological Bulletin*, as well as the Annual Reports and Announcements.

The service which the Laboratory has rendered to biological instruction in our schools and colleges and to advanced work in biology in general is incalculable; it is the biological clearing house of this country, where the specialist who has been unable to keep up with the general advance of his science may learn from others what has been transpiring in fields outside his own, where teachers may exchange ideas as to the best methods of instruction, where distinguished men in various fields come to know each other in the most intimate and helpful way, and where all may get broader and truer ideas of the great problems of biology. The Laboratory is also a place to which schools, colleges and universities are coming to look for good men. This feature has never before been emphasized and it receives no direct attention at Woods Hall, but if the indirect influence of the Laboratory in discovering good men and placing them in good positions were known, it would be seen that this feature is no small part of the service which the Marine Biological Laboratory renders to American biology.

The confidence of the Director that the Laboratory would not fail to receive the support of the schools, colleges and universities of the country has been fully justified. During the past twelve years representatives from about three hundred schools and higher institutions of learning have been in attendance at the Laboratory, while twenty-seven colleges and universities and three societies have been regular subscribers to Rooms and Tables. The Laboratory has now grown to such proportions that it cannot expect to draw any large part of its financial support from educational institutions, already overburdened. It is itself an educational and scientific institution of highest rank, and however measured, deserves to stand alongside the best scientific schools and laboratories of the world. "It is acknowledged that only one similar institution in the world (Naples) is more productive in original research, and no other offers even approximately equal advantages for instruction." Such an institution deserves and expects independent support.

The present financial condition of the Laboratory is shown by the following figures:

Total Assets.	
Estimated value of real estate, buildings and equipment at Woods Holl	$35,000.
Invested Funds.	
General Endowment	$ 4,553.
Lucretia Crocker Fund	2,500.
Library Fund	866.
Interest on hand	230.
	$43,149.
Total Liabilities.	
Mortgage on Woods Holl property	$2,900.
Unsecured Loans	5,276.
	$8,176.
Assets less Liabilities	$34,937.

The total earnings of the laboratory as compared with its expenses are given herewith. ('Earnings' include all sources of income save donations only; 'expenses' include all disbursements save those for land, buildings and permanent equipment.)

Total Donations	$37,730.
Earnings	$47,919.
Expenses	$50,759.

It appears from this statement that the income of the Laboratory, like that of scientific and educational institutions in general, is scarcely sufficient to meet the running expenses, and that it must look to the donations of interested friends for assistance in meeting a small annual deficit and for all permanent equipment and enlargement. This is a fact which requires no apology; the Laboratory is not a commercial enterprise but a charitable institution, in the same sense that colleges and universities are such. It is not the purpose of the Laboratory to make money, but rather to contribute as much as possible to the advancement of science, and in this respect it has fulfilled the highest hopes of all its friends. There is every reason to be proud of the fact that it has accomplished so great a work on so small a financial basis, and that it is at present so nearly self-supporting as it is.

The Trustees at their meeting in New Haven, December 29th last, resolved that for the best interests of the Laboratory the out-standing debt of $8,176, should be paid off at once and that a small cash balance should be left in the hands of the Treasurer. They, therefore, appeal to the friends of the Laboratory to contribute $10,000 to this end. Subscriptions may be sent to the Treasurer, D. Blakely Hoar, 220 Devonshire Street, Boston, or to any member of the Board of Trustees.

The time has come also when to give the Laboratory the stable and permanent character which it deserves it should be liberally endowed. Where could a better investment be made than in a scientific and educational institution with such a history behind it and such excellent prospects before? The Laboratory and the ideals for which it stands must not be allowed to suffer for lack of support; it must not remain standing where it is, for although its success has been remarkable, it is only the beginning of what it should and could do, if properly supported. The aim of those who are interested in its welfare is to create a permanent station with adequate endowment and equipment which shall be in the future yet more than in the past 'a national center of research in every department of Biology.'

For this end its friends labor and wait, hoping that the time is not far distant when generous friends of science and education will see its needs and its opportunities and will not be slow in their response.

E. G. CONKLIN.
UNIVERSITY OF PENNSYLVANIA.

REPORT ON THE INITIAL WORK OF THE STATE GEOLOGICAL SURVEY OF NEBRASKA.*

IN a State such as Nebraska where there is no 'mineral'—a term which in the west has come to mean gold and silver-bearing—it is difficult to convince the masses that there is the least possible economic importance in a State geological survey.

If 'mineral' did occur, apathy could much more easily be overcome, and the appeals for a survey would find more willing and receptive ears. But something stronger than apathy is encountered in the prejudice which has been engendered against a State survey by men who have sought heretofore to establish such for the evident purpose of holding office, that is make a political job of it. This prejudice seems justifiable, nevertheless it is none too easy to live down. A good many years have passed since our admission to Statehood, yet Nebraska, a commonwealth greater than all New England, has never made an allowance of any kind for a State survey, not even for the postage and stationery used in correspondence. Literally then not so much as one cent has ever been voted for such work to date. Even moral support has been withheld, save that the titles Acting Botanist, Acting Chemist and Acting Geologist have been conferred. The title being the sole emolument of office. However, the preliminary work of a survey, which has engaged the writer's attention for successive summer vacations since 1891, has just received from the University of Nebraska encouraging recognition, and an allowance, which, though small, is substantial. For the biennium of 1899 and 1900, $1000 was allowed by the Board of Regents for the initial work of a State geological survey. The same sum was likewise allowed for a botanical survey. The sum of $500 a year may seem ridiculously small, yet it made it possible to undertake several lines of work, and fair progress may be reported. Camp outfits were obtained for several field parties. Team and camp accoutrements were procured for Mr. Cassius A. Fisher, a Fellow in the department of geology, who, together with Mr. W. H. H. Moore (U. of N., 1900), constituted a party whose summer was to be spent in examining gravel pits, clay pits, quarries, the water supply, and geology of the southeastern or Carboniferous counties of Nebraska. At each quarry, pit and exposure photographs were taken, measurements and sections made, notes recorded, and liberal samples taken from the soil and sub-soil down through every layer.

One hundred and fifty localities were thus examined. The specimens from each quarry are being mounted in order upon large wooden tablets properly made and finished, each some 7 feet high by one foot wide; these as done are placed permanently on exhibition to illustrate the rock and clay resources of the State. A second party in charge of Mr. C. N. Gould (a Fellow in the department of geology), with Mr. Roy Hadsel (S. W. Kan. College, 1899), as assistant, was provided with team and camp outfit, and drove from Oklohoma through

* Paper read before the Nebraska Academy of Sciences, December 1, 1899.

Kansas, Nebraska, northwestern Iowa into South Dakota, following the Dakota Cretaceous, the great water-bearing beds of the plains. Over one hundred boxes of material were collected, with the result that new forms were found, some valuable rock-bearing beds located, and the second or third largest known collection of Cretaceous leaves made, numbering 4000 to 5000 specimens. Mr. Gould is devoting his undivided energy to these collections, working them out, recording and numbering them, classifying and describing them. This work is to be finished by July 1, 1900.

A third party consisted of Mr. G. E. Condra, a graduate student of the University of Nebraska, who spent the spring and summer collecting the fossil Bryozoa in the Carboniferous exposures, with the result that some 30 localities were visited and a large collection made, in which are already represented over 40 species, several forms being undoubtedly new. Mr. Condra will spend the remainder of the year upon his collections, preparing the material, numbering, recording, identifying and describing the same. Numerous microscopic sections are already cut, and as many more are to be prepared, and this work which was begun two years ago will be continued for at least another year before a paper is to be presented.

A fourth party, consisting of Miss Carrie A. Barbour, assistant curator of the State Museum, and an assistant, visited quarries in the Carboniferous, and Permian for the sole purpose of collecting fossils. Over 20,000 of the commoner species were procured, some of them apparently new to the State, with three or four species supposed to be undescribed. A fifth party consisted of the acting State Geologist, who visited all quarters of the State, and attempted to correlate work as far as he was able. There is such an accumulation of data and material that it will tax the department to dispose of it in time to begin the work of 1900. Besides, several lines of investigation are under way, the most noteworthy of which is that of Mr. W. W. H. Moore, who is making freezing and pressure tests of the mortar, cement and building rocks collected during the summer. This investigation bids fair to yield some useful if not important results. It is the intention that every line of work and investigation shall be so well finished and so nearly in hand that there will be little or no overlapping of the work of one year upon the next. It may be reported that the initial work of the survey seems to be as well systematized as is to be expected the first year. Barring unexpected difficulties and adversities, it seems assured that fair progress may be reported to this academy at the close of the present biennium.

Another sum of $500 will be available for a continuance of the work in 1900, and not less than five or six papers will be ready to submit to the Legislature, as the result of the work of the first biennium. The plan being to ask for a special appropriation for publishing. These papers, according to present intention, will be confined studiously and strictly to economic phases of our geology, with the hope and full expectation that a legislative as well as a university appropriation may be a reality for the second biennium.

The University of Nebraska.

SCIENTIFIC BOOKS.

Text-Book of Vertebrate Zoology. By J. S. Kingsley, Professor of Zoology in Tufts College. New York, Henry Holt & Co. 1899. 8vo., pp. viii + 439. 378 figures in text.

Professor Kingsley has prepared a text-book for college students "intended," so says the preface, "to supplement both lectures and laboratory work and to place in concise form the more important facts and generalizations concerning the vertebrates." The first half of the four hundred odd pages of text is taken up with an account of the morphology of the vertebrates, while the second half is devoted to a systematic review of the group.

In the first half an introductory four pages defines and illustrates the group of chordates and the position of the vertebrates in the group. There follow four pages of introductory embryology, dealing in the briefest and most generalized way with the pre-embryonic stages of development, and then eight pages of general histology.

The organs of vertebrates are then considered under the four heads of entodermal, ectodermal, mesothelial and mesenchymatous organs. The discussion of each is from the embryological standpoint, but includes a consideration of its adult structure. The space given to an organ is necessarily very little, to the teeth two pages, to the tongue half a page, to the cranial nerves eight and one-half pages. This part of the book closes with an account of the segmentation of the head, followed by a brief account of the early development of the egg of vertebrates (oögenesis, spermatogenesis, cleavage, gastrulation) and by a section on the origin of the vertebrates. If one should weave into a single account greatly condensed resumés of Wiedersheim's 'Comparative Anatomy' and Hertwig's 'Text-Book of Embryology,' the result would be very much that which we have here, though Professor Kingsley's combination is skillfully made, clear, generally accurate and brought up to date.

The author is to be congratulated on having the courage to give due recognition in the second part of his book to the importance of a knowledge of vertebrate classification. It is further a matter of congratulation that fossil forms have been included. The treatment is the usual one and this part of the book in its arrangement and general typographical make-up reminds one strongly of Sedgwick's translation of Claus's elementary text-book. It is not to be expected that Professor Kingsley has pleased every one in the matter of classification, that he has prepared a concise and useful summary few will question. Families are briefly characterized; important genera are mentioned; in some cases habitat and common names of genera are added, in other cases only the scientific names appear. But few specific names are mentioned. It is unfortunate that the plan of the book renders this part of it so brief. For purposes of identification it cannot be of great use, but as a convenient means of referring generic names to their families it is of distinct value, and hence the mention, merely, of many generic names is to be commended.

That a book meant for college use should omit references to the literature is a serious blemish.

The index, unfortunately, includes the anatomical and embryological references for the first part of the book only, and the taxonomic terms for the second part only. Thus Cladoselache is referred to page 237, but not to page 173. Even taxonomic terms used in the introductory sections of the systematic part of the book are not fully indexed. Thus Notodelphys is referred to page 287, but not to page 281, where it also occurs; while Rhinoderma, which occurs on the same page, is not indexed. This should be corrected in a later edition.

Among many old friends we find some excellent new illustrations, and many that are rough sketches. Particularly noteworthy are the very useful perspective diagrams, such as Fig. 127. Why, on the other hand, Fig. 16, should be thought worth printing, when so many excellent figures are available, is a mystery. The reproduction of the original figures is frequently bad, the reference lines and letters being often blurred, the latter sometimes illegible. (Figs. 34, 39, 85, 159, 283.) The copied figures are excellently rendered and in other respects the work of the publishers is well done.

Detailed criticism is perhaps superfluous where so much is good, but one wonders how Professor Kingsley overlooked this (p. 25) with reference to the air bladder of the fishes: "The bladder itself usually lies dorsal to the aorta and urinogenital system next the vertebral column." Does not every fisher-boy know better? That archenteron and stomach are synonymous terms, as implied on page 6, and that the duodenum is pre-hepatic, as one might infer from reading the statement at the bottom of page 35, are statements needing revision.

The style of the book is on the whole simple and clear (what does the subject-matter admit of else?), but one is occasionally startled by such English as this (p. 38): "In birds, at about the middle, the mid-gut bears a blind tube," or as this (p. 223): "The lampreys feed upon the mucus and blood which they *rasp* from fishes."

The method of treatment is then strictly morphological—the first part dealing with the morphology of the organs—the second part adding to this so much of external morphology as is of use in classification. Judged as a morphology the book deserves to be commended. But does this warrant the author in calling it a zoology?

A categorical description of the structures of vertebrates so arranged as to suggest their evolution is but a part of zoology. In the opinion of the reviewer it is the least interesting part, and by many modern workers it is regarded as the least important. It would be hard to imagine a college student calling Professor Kingsley's book either interesting or stimulating, though if used as directed in connection with lectures and laboratory work he will surely find it of value. It is easier to point out faults than to show how they may be remedied, but why, may we ask, should three pages be given to the mouth, lips, teeth and tongue, and no word said of the chain of causal relations connecting lip development in mammals with the power of mastication, heterodont dentition and articulate speech, so admirably worked up by Gegenbaur? Why an account of the peculiarities of structure of the Raiæ and no word as to the relation of these peculiarities to the mode of life? And so the rest of it: if we are to have pure morphology, why not more of the spirit of Gegenbaur and less of that of Haeckel? When the ideal text-book of zoology is written it will surely deal with causes, not merely with results.

Jacob Reighard.

University of Michigan.

Water-Supply Engineering: The Designing, Construction and Maintenance of Water-Supply Systems, both City and Irrigation. By A. Prescott Folwell, Associate Professor of Municipal Engineering in Lafayette College. First Edition. New York, John Wiley and Sons. 1900. Octavo, 562 pages and 19 plates. Price, $4.00.

The Filtration of Public Water-Supplies. By Allen Hazen. Third Edition, Revised and Enlarged. New York, John Wiley and Sons. 1900. Octavo, 321 pages and 22 plates. Price, $3.00.

It is a happy feature of American engineering education that many of the text-books used by the student are also manuals constantly consulted by the engineer in making his designs. In such a system of education there is no conflict between theory and practice, but each supplements and improves the other. Theory is indeed merely the systematic formulation of general laws derived from experience, and practice is the application of theory to the economic production of useful results. Both of the above books are well adapted to class use, both exhibit the details of the latest theories and constructions, and both are of high value to the practicing engineer. The first book covers the wide field of all the features of water works, while the second treats of that special part concerned with the improvement of the quality of the water.

Professor Folwell has succeeded well in presenting the principles and practice of this wide field in a single volume. The theoretical discussions may sometimes be criticised as rather incomplete, but it is evidently intended that the reader should have a good knowledge of applied mechanics and hydraulics. The question of the force of impact caused by a moving body or stream of water, which is always puzzling to practical men, especially needs correction and revision on pages 229 and 247. On the whole, however, the theory seems as well presented as can be done in such limited space. The practical details relate largely to the water supplies of cities and towns, irrigation systems being properly given a subordinate place. The subject of designing which includes quantity and quality of water and the details of the systems of collection, purification, and distribution, covers 452 pages, while construction and operation are treated in 94 pages. Methods of cleaning water mains, of thawing out frozen pipes, and of preventing corrosion from electrolysis are well discussed. Pumping systems are treated more fully than usual; this is a step in the right direction, since about 75 per cent. of the water works of the United States are operated by this method, the gravity systems being largely confined to the large towns on the Atlantic and Pacific States. The growing importance of water-supply engineering may be clearly recognized from the fact that the number of water works in the United States in 1898 was about 1600, while in 1897, it was about 3200. The book is well illustrated, clearly written, and will be a valuable aid to all who are planning or operating public water supplies.

The increasing interest in securing purity of water-supplies is not only evidenced by the circumstance that the book of Mr. Hazen has reached its third edition in less than four years, but also by the construction of sand filter beds at seventeen American towns and cities in the last decade. During the same period more than one hundred others have installed mechanical filtration plants. No fact in sanitary engineering is, indeed, more fully established than that the death rate from typhoid fever is materially lowered by filtration, and the present interest of the public gives hope that the time is not far distant when the cities of the United States may take rank with London, Berlin, Vienna, and Amsterdam in freedom from that disease. Mr. Hazen is a high authority on this subject, and, although an advocate of the system of slow filtration through sand beds, his book treats also of the more rapid system of mechanical filters, which in many cases may be installed at less expense. The present edition gives the results of the recent experiments at Louisville, Pittsburg, and Cincinnati, and also valuable information regarding the filter beds of several European cities. Statistics of both systems of filtration are presented in tabular form. These show that the slow sand system is used by cities having an aggregate population of 21,400,000, of of which 10,200,000 are in Great Britain and 260,000 in the United States. The aggregate population using mechanical filters in the United States and Canada is nearly 1,600,000, while this system is practically unemployed in other countries. At the present time only about one-tenth of the cities and towns of the United States have filtered water supplies. The book of Mr. Hazen, as well as the large plant recently built at Albany, N. Y., under his supervision, will have much influence in inducing other cities to inaugurate effective methods for the purification of their water supplies.

MANSFIELD MERRIMAN.

California Mines and Minerals. Published by the California Miners' Association, under the direction of EDWARD H. BENJAMIN, Secretary for the California Meeting of the American Institute of Mining Engineers. San Francisco, Calif. 1899. Vol. 8. Pp. 450.

This treatise upon the mines and mining of California is dedicated to the members of the American Institute of Mining Engineers 'as a souvenir of their visit to California' in September and October, 1899; but it is a vastly more important and valuable work than the usual 'souvenir.' It constitutes a very valuable treatise upon the great industry to which it is devoted and is full of important information, valuable historical facts and industrial statistics. It is a large volume, handsomely printed, extensively and well illustrated, well made and substantially bound. Its market value is stated to be five dollars and the munificence of the Californian is well exhibited in the fact that a copy was supplied to every member of the visiting Society.

The contents consist of thirty-five papers by well-informed writers and often the ablest in their respective departments. In these chapters are described the topography, geology and mineral deposits of the various mining counties of the State, the methods of working, the statistics of production, and the special conditions of exploitation and development of the more interesting fields, especially those in which the precious metals are produced in largest quantity. Regarding the most important products, gold and silver, copper, borax, bituminous and asphaltic rock, quicksilver, and petroleum, the ground is remarkably well covered. We note that the output of silver has less value than that of petroleum and that quicksilver has fifty per cent. larger value than the former.

Numerous half-tone and other illustrations, maps and tables of statistics aid the reader in obtaining a most satisfactory understanding of the extent and importance of the mining industries of California.

BOOKS RECEIVED.

Richter's Organic Chemistry. Edited by PROFESSOR R. ANSCHÜTZ. Translated by EDGAR F. SMITH. Third American Edition. Philadelphia, P. Blakiston's Son & Co. 1900. Vol. II., pp. vi + 671. $3.00.

Malay Magic. WALTER WILLIAM SKEAT. With preface by C. O. BLAGDEN. London and New York, The Macmillan Company. 1900. Pp. xiv + 665. $6.50.

Lessons in Elementary Physiology. THOMAS H. HUXLEY. Edited by FREDERIC S. LEE. New York and London. 1900. Pp. xvi + 577.

The Teaching of Elementary Mathematics. DAVID E. SMITH. New York and London, The Macmillan Company. 1900. Pp. xv + 312. $1.00.

SCIENTIFIC JOURNALS AND ARTICLES.

The Plant World for February has for its leading article 'Notes on the Edible Berries of Alaska,' by Walter H. Evans, who states that they are of wonderful abundance and variety. John M. Coulter treats of the 'Geograpical Distribution of Conifers,' Byron D. Halsted presents a note on 'Coloration of Leaf for Seed Distribution,' and K. C. Davis discusses the 'Wild and Garden Pæonies in America.' Mrs. Caroline A. Creevey continues her series of articles on 'Plant Juices and their Commercial Values,' amber, copal and turpentine being among those discussed in this number. The Supplement on 'The Families of Flowering Plants' contains the Ginkgoales, the Pinaceæ and the Taxaceæ.

SOCIETIES AND ACADEMIES.

GEOLOGICAL SOCIETY OF WASHINGTON.

THE 97th regular meeting was held at the Cosmos Club, February 14, 1900.

Under informal communications, Mr. Bailey Willis stated that a diamond drill hole at The Dalles, on the Columbia River, had reached a depth of 916 feet and had penetrated several flows of Columbia basalt, distinguished by layers of clay and by differences of texture. No exact section has been kept. A piece of core from 916 feet in depth is shown by examination in thin section to be basalt. The object of the boring, which is a private enterprise, is to prospect for coal.

Mr. H. W. Turner proposed the adoption and use of the term *Sierran*, originally suggested by Professor Le Conte, to distinguish the erosion interval of the early Pleistocene. The actuality and importance of this early Pleistocene erosion were illustrated with reference to the eastern slope of the Sierra Nevada. It was shown that the *Sierran* cañons had in some cases been occupied by lava flows upon which the moraines of Glacial time are resting.

The following papers were presented on the regular program:

(1) 'A peculiar Clastic Dike and its Associated Ore Deposits,' by Mr. F. L. Ransome. This dike is exposed in the workings of the Wedge and Bachelor mines, near Ouray, Colorado. It fills a normal fault-fissure, of small throw, cutting nearly horizontal beds of sandstone and shale. The filling material came from above, and is largely composed of flakes of black shale, derived from a bed which is traversed by the fissure, but which limit the upward extension of the dike. This material was subsequently forced by pressure into all the branches of the fissure and has the form of an eruptive dike. It has been explored to a depth of 630 feet and has an average width of 2 or 3 feet. The ore, which is an argentiferous tetrahedrite, or freibergite, occurs alongside of, or in the dike, in spaces opened by later movements. These have been in part bedding faults, which have dislocated the dike along nearly horizontal planes.

(2) 'Wood River Mining District, Idaho,' by Mr. Waldemar Lindgren. The silver-lead mines of Wood River are located in southern central Idaho, some 50 miles north of Snake River. The geological formations consist of a sharply folded series of Paleozoic, probably very largely Carboniferous, sediments consisting of limestones, quartzites, and slates. Imperfect fossils indicating Upper Carboniferous were found in it at two localities. The large granite area of southern Idaho abuts against the sedimentary

rocks in this vicinity, showing at the contact undoubted intrusive phenomena. The Carboniferous series contains several isolated masses of granitic rocks of varying character, which are also intrusive into the sediments.

The deposits are fissure-veins with a west to northwesterly strike and southerly dip, occurring, as a rule, in the calcareous shales of the sedimentary formation. The principal minerals are galena and zincblende in a gangue of predominating siderite. Veins of the same character are also found in the granite areas enclosed in the sediments. The veins are pre-Miocene and post-Carbonifereus in age, their crossings being in part covered by andesitic flows. The granitic rocks also contain another series of veins of very different composition. They carry chiefly gold contained in pyrrhotite, chalcopyrite, pyrite, and arsenopyrite. Replacement has played an important part in the vein formation, especially in those veins which are contained in the sedimentary areas. The fissure plans are well defined but the ore-bodies do not follow these strictly in detail, and may exhibit considerable irregularity.

(3) 'Cretaceous fossils collected by J. B. Hatcher in Patagonia,' by Mr. T. W. Stanton. Among the collections brought back by Mr. Hatcher's last expedition to Patagonia there are some Cretaceous invertebrates that seem to represent a fauna new to South America. The localities from which they were obtained are near Lake Puerrydon in Latitude 47° 30′ S. and Longitude 72° W. There are about 35 species in the collection of which 28 are sufficiently well represented to be described and these all appear to be new. Although there are some indications of relationships with Lower Cretaceous faunas, consideration of the collection as a whole leads to the conclusion that the horizon is about the middle of the Cretaceous, at least not lower than the Gault.

F. L. RANSOME,
DAVID WHITE,
Secretaries.

BIOLOGICAL SOCIETY OF WASHINGTON.

THE 318th meeting was held on Saturday, February 10th. H. J. Webber exhibited photographs of the Melon Pawpaw, *Carica papaya*, which is a native of both the East and West Indies. The form native in Florida has a fruit about the size of an egg, but the cultivated varieties (of which there are several) bear fruits from the size of a small musk melon up to five or ten pounds in weight. The fruit is pyriform and much resembles a musk melon in taste and make-up and is sliced and eaten in the same way.

The most noteworthy character of the plant is its well known faculty of rendering meat tender when cooked with it. This is due to the presence of a soluble ferment known as papain which is similar in action to the animal pepsin. The fruit of *Carica* also contains this ferment in considerable quantity and bids fair to become a very valuable desert fruit, especially for invalids troubled with indigestion. It is a fruit which should be more widely known and sold in all markets.

Henry W. Olds spoke on 'Form in the Songs of Birds,' showing first that the study of bird music, while interesting, is of little, if any, value as an aid to the development of the science of ornithology. He then considered the question of the use of our scale. He gave a brief resumé of its evolution and stated that, wonderful as it seems, it is a fact that some of the birds do use our scale. He instanced several that unmistakably are governed by the intervals that compose it, although some of them occasionally wander from the key just as human singers do. Mr. Olds then considered various essential forms that give to music coherence and capability of æsthetic satisfaction. These he illustrated with blackboard notations and whistled examples of both human and avian music. He showed different means by which is produced that symmetry that is needed to satisfy the musical sense—the regular recurrence of phrases or kinds of phrases, repetition of one theme on different pitches, the regularity of these repetitions, antiphonal or answering themes, etc., and for every example in our music instanced its counterpart among bird songs he had noted. In conclusion he suggested that these were not accidental resemblances, but seemed to show on the part of the birds intelligent appreciation of musical effects; and that there appeared to be no escape from the conclusion that the birds were subject to a musical evolution that paralleled our own.

Mr. M. G. Kains presented a paper upon 'The Effects of the Electric Arc Light in the Culture of Easter Lilies,' giving the results of experiments conducted during the winter of 1895, at Cornell University, under the direction of Professor L. H. Bailey. Three divisions of the plants were made, one in the full glare of the naked light, one in which the light first passed through a pane of glass, and one where no light was employed. The light burned nightly for four months and uniform cultural conditions were maintained throughout the tests. Plants in the light sections were taller, blossomed earlier, were less robust and their flowers shorter lived than those grown in the dark, blossoms in the naked light exhibited a dark brown burn upon the surface facing the lamp, and blossoms upon plants grown in the dark lasted two days longer than those in the light. From the experiments it is concluded that commercial use might be made of the arc light after the lily buds are an inch long, and that the light must pass through a glass to screen out the ultra-violet rays of the spectrum.

E. V. Wilcox discussed 'Lupines as Plants Poisonous to Stock,' saying that cattle and sheep varied greatly in their liking for the growing plants, some animals eating them with avidity and others caring little for them. The poisonous properties of the Lupines appeared to reside in the seeds or seed pods, for, while the plants were usually eaten with impunity, great mortality had been known to occur among stock which was forced by a fall of wet snow to feed on plants from which the leaves had mostly fallen while the seed pods remained. On the large ranges of the west, where forage plants were not cultivated, Lupines were frequently so abundant that they were cut and dried like hay for use in winter, and the speaker noted a case where sheep fed on this Lupine hay were seemingly driven mad.

T. W. Stanton,
Secretary.

THE PHILOSOPHICAL SOCIETY OF WASHINGTON.

The 512th meeting of the Society was held on February 3, 1900, at the Cosmos Club. After a general discussion on the method of publication of the *Bulletin*, the first regular paper of the evening was read by Mr. J. G. Hagen, on 'Recent Progress in Astro-physics.'

During the course of the address the following three points were discussed: *The cluster type* of *variable stars*, the *spectroscopic binaries*, and the *Potsdam photometric catalogue.*

Regarding the first point, the cluster Messier No. 5 was mentioned as presenting a remarkable uniformity in its variable stars. Out of 900, visible on the plates obtained in Arequipa with the 13-inch Boyden refractor, 63 were recognized as variables, and 40 of them were measured accurately from nearly a hundred plates. The mean period of all except two is about 12½ hours, with a mean range of 1.1 magnitude. It was suggested that, with Pogson's light factor 0.4, the common range of 1.1 magnitude could be explained by supposing each variable to be a binary system, with components of equal brightness. The cluster would then consist of many binary systems, each with its orbital plane passing through the sun, and with a period of revolution equal to 25 hours.

With respect to spectroscopic binaries, Campbell's discovery of Polaris as a double system was mentioned. The center of gravity approaches our sun with a velocity of 12 kilometers, while Polaris oscillates around it in a period of about four days. The fact that three years previous the mean velocity was found eight kilometers larger, might point to a disturbing body. Yet, to pronounce Polaris a triple system, would be premature. Another interesting discovery of a periodic change in the spectrum was recently made by Mrs. Fleming in the case of Zeta Centauri, with intervals of two and six days, thus making a period of eight days. The intervals of two and six days were graphically illustrated by an eccentric orbit. Attention was also called to experiments made by Humphrey, Mohler and Wilsing, to the effect that changes in the normal spectrum may be produced by changes of pressure in the source of light.

The third point consisted in a summary of a review of the Potsdam photometric catalogue, recently published in the *Vierteljahrsschrift*, XXXIV., pp. 288–297.

At the close of the paper two Goerz Trieder Binoculars were exhibited.

The second paper read was by Mr. J. F. Hayford, on 'Recent Progress in Geodesy.' As it is expected that this will soon be published in SCIENCE in full, no abstract is here given.

A paper by Mr. T. J. J. See, on 'Recent Progress in Astronomy,' went over to the next meeting on account of the absence of the author.

E. D. PRESTON,
Secretary.

TORREY BOTANICAL CLUB.

THE annual meeting on January 9th, resulted in the election of the previous board of officers, including as *President*, Hon. Addison Brown; *Treasurer*, Maturin L. Delafield, Jr.; *Secretary*, Edward S. Burgess, Ph.D.; *Editor*, Lucien M. Underwood, Ph.D. Annual reports of officers were rendered, that of the Treasurer showing a balance in the treasury.

The Secretary, Professor Edward S. Burgess, reported an average attendance of 31 at the 15 meetings held during the year, one death, a present active membership of 237, corresponding membership 142, honorary membership 3, total membership 382. Among the 18 scientific papers presented, 5 had been accompanied by lantern views; 4 papers related to ferns. Nine illustrative exhibits of photographs, plates and flower paintings, etc., had been held. Brief reports of collections and of botanical progress numbered 55.

The editor, Professor L. M. Underwood, reported the regular monthly issue of the *Bulletin*, forming the largest volume published to date, including 650 pages, besides 23 heliotype plates and 38 figures in the text, and including 65 articles representing 39 authors. The publication of the *Memoirs* has been carried on with unusual activity, including Dr. M. A. Howe's monograph on the Californian Hepaticæ (208 pages, 35 plates), Mr. Tracy E. Hazen's Life-history of '*Sphærella lacustris* (*Hæmatococcus pluvialis*'), pp. 33, 2 colored plates, and the beginning of Professor F. E. Lloyd's 'Comparative Embryology of the Rubiaceæ' (pp. 21, 4 plates).

Miss Ingersoll, as curator, reported upon the condition of the herbarium of the Torrey Club, suggesting its transfer to the New York Botanical Garden. Discussion followed looking toward its treatment there as the nucleus for a distinct local collection, but no definite action was taken. Dr. T. F. Allen remarked upon the beginnings of the collection as dating from a persistent botanical exploration of parts of New Jersey, especially about New Durham and the Secaucus swamps, made by himself and Mr. Wm. H. Leggett, Dr. Bunstead, etc.

Dr. Allen's own private herbarium at Litchfield, Ct., is also richly representative of those localities and others now destroyed or altered, and contains much of interest to the history of local botany of New York City.

Miss Marie L. Sanial, as Secretary of the Excursion Committee, reported 38 excursions held, with the new feature of excursions for bryological and other collections in December, at one of which 15 persons were present.

The Committee appointed to consider a program for a Torrey Day in connection with the A. A. A. S. meeting here next summer, reported through the Secretary, a provisional program.

The scientific paper of the evening was by Professor Francis E. Lloyd, on 'The Relationships of certain Rubiaceæ,' forming part of an investigation in the embryology of that order now in course of printing among the *Memoirs* of the Torrey Club. The ground of relationship considered was the ovary, which is classed as inferior, but developmentally proves a receptacle hollowed out. The flower seems to be derived from one or more separate corolla-lobes. The Rubiaceæ are very polymorphic externally, and there is the greater need of discovery of stable internal characters. Such characters for the ovary of the Stellateæ were discussed in detail. That of the common Buttonbush, *Cephalanthus*, was alluded to as possessing certain ovary characters in form and relatively rapid and prolonged growth of the basal partition, which accord most significantly with the unusually compressed position of the ovary.

Discussion followed regarding the passage of pollen tube through tissues rather than loosely in the cavity of the ovary. In some Rubiaceæ, said Professor Lloyd, these tubes seem stimulated by contact with the enlarged collar-cells of the funiculus, and appear to owe their guidance into the micropyle to such stimulus. Dr. MacDougal remarked upon recent conclusions that pollen tubes show negative reactions to oxygen, but positive to sugars, and to albuminoid substances in the ovary or near the embryo-sac.

Edward S. Burgess,
Secretary.

THE NEW YORK SECTION OF THE AMERICAN CHEMICAL SOCIETY.

The February meeting of the New York Section of the American Chemical Society was held at the Chemist's Club, 108 West 55th street, on Friday evening, the 9th inst., Dr. C. F. McKenna presiding. After consideration of a series of resolutions submitted by the Committee on Standards for Instruments of Measure, the following papers were read: 'The Technical Analysis of Rope and Twine,' by Durand Woodman; 'A New Synthesis in the Phen-Miazin Series,' by Marston Taylor Bogert; 'On the History of Photo-Chemical Improvements,' by Maximilian Toch.

Dr. Woodman described the chief commercial grades of Cordage, 'oiled' and 'unoiled,' 'tarred,' 'plumbagoed,' etc., and exhibited samples of manila, sisal and jute fiber with analyses; also analyses of the different grades of rope above mentioned.

Dr. Bogert described a new method of preparing the salts of the Phen-miazin series as developed in the organic laboratories of Columbia University, which consists in heating anthranilic acid with any nitrile in a sealed tube for several hours at a temperature of 200 degrees to 250 degrees C., according to the nitrile used. Since many foreign chemists, as well as several in this country, are working on this same subject, it is very gratifying to have a successful result on a new line of experiment from the University in this city.

Mr. Maximilian Toch described chiefly the progress in photo-chemistry, and illustrated the method of printing and developing some of the more rapid bromide papers. His paper was listened to with great attention and was followed by remarks and reminiscences from several members

Durand Woodman,
Secretary.

THE ACADEMY OF SCIENCE OF ST. LOUIS.

At the meeting of the Academy of Science of St. Louis of February 5, 1900, some 250 persons were given a demonstration of the use of the microscope in the sciences, arts and industries, by experts, under the direction of Dr. H. M. Whelpley, as follows:

Anatomy, Dr. R. J. Terry; *Bacteriology*, Dr. Amand Ravold; *Blood examination*, Dr. Ludwig Bremer; *Botany*, Mr. H. F. Roberts; *Diseases of forest trees*, Dr. H. von Schrenk; *Drug adulterations*, Mr. O. H. Elbrecht; *Flour inspection*, Mr. Victor Goetz; *Insects parasitic on man*, Mr. C. F. Baker, *Living protoplasm*, Dr. Otto A. Wall, Jr.; *Microphotography*, Mr. Robert Benecke; *Mineralogy*, Dr. G. Hambach; *Photographic dry plate testing*, Mr. Robert Benecke; *Photomicography*, Dr. Adolph Alt; *Physiology*, Dr. Hartwell N. Lyon; *Seed adulterations*, Mr. F. W. Maas; *Spice adulterations*, Mr. William K. Ilhart; *Textile fibers*, Mr. Peter J. Weber, Jr.; *Trichina*, Dr. G. C. Crandall.

Through the courtesy of the Historical Society, the rooms of that Society were thrown open to the members of the Academy and their guests, and the Society's important collections, as well as the demonstration offered by the Academy, proved a source of interest and instruction to the ladies and gentlemen present.

William Trelease,
Recording Secretary.

NOTES ON PHYSICS.

DRUDE'S ANNALEN.

A new series (the fourth series) of the *Annalen der Physik*, begins with the current number, January, 1900, under the editorship of Paul Drude. This great periodical will now be known as *Drude's Annalen*. The third series, the *Annalen der Physik und Chemie*, edited by G. and E. Wiedemann, contains sixty-nine volumes. The entire series, 305 volumes to date, represents a large part of the progress of the physical sciences during the eighteenth and nineteenth centuries.

RADIANT HEAT.

Professor Max Planck gives, in *Drude's Annalen*, January, 1900, a reprint of his electro-magnetic theory of radiation which was communicated to the Berlin Academy of Sciences in May, 1899. This memoir, which seems to be monumental in character, is remarkable in that it verifies the Stefan-Boltzmann law, derived from thermodynamic considerations, that the total energy radiant from a black body is proportional to the fourth power of the absolute temperature, and the law of W. Wien concerning the distribution of energy in the spectrum of a black body.

Wien's conclusions are based upon certain assumptions as to the number of radiant centers (molecules) in unit volume and their velocity. It is now known that the total energy radiated from a black body and its distribution in the spectrum depend only upon temperature and are entirely independent of the physical properties of particular substances, so that it is highly probable that the law of total energy and the law of its distribution in the spectrum are capable of rigorous derivation from assumptions of axiomatic simplicity.

The theoretical results of Stefan, Boltzmann and Wien, now verified by Planck, may, therefore, eventually appear to be independent of the highly specialized character of the assumptions upon which they are based. When this stage of the science is reached, these laws of radiation will no longer appeal to experiment for verification, but they will take their place among numerous other established laws as instruments for the interpretation of experimental results.

Physicists ought to drop the term radiant energy and retain the older and better term radiant heat, inasmuch as the energy of radiation is heat in the same sense that molecular energy is heat. Both types of energy are subject to the first and second laws of thermodynamics; both types give rise to the entropy function, and Maxwell's law of molecular velocity distribution is strictly analogous to Wien's law of the distribution of energy in the spectrum.

THERMAL CONDUCTIVITY.

HEAT measurements are among the most inaccurate of physical measurements and the measurement of thermal conductivity is perhaps the most inaccurate of the measurements in heat. Professor Kohlrausch (*Drude's Annalen*, January, 1900) proposes a method for measuring thermal conductivity which depends upon the final permanent distribution of temperature in a conductor carrying electric current, heat being allowed to flow out of the conductor only at the points where current enters and leaves it. Under these conditions a remarkably simple relation subsists between the temperature at a point, the electric potential at a point, and the ratio of electrical to thermal conductivity. The method depends only upon measurements of temperature, of electrical potential, and of electrical conductivity. W. S. F.

ENGINEERING NOTES.

A NUMBER of European nations are now adopting the Gruson chilled iron shield for their land defences and the success of the invention is so well-assured, it is said, that the Messrs. Krupp, some time since, bought the *Grusonwerke* and have developed the invention to a state of considerable perfection. The Gruson armor-turrets are thought to be practically invulnerable; their flatly curved tops deflecting shot and shell and their adamantine chilled surfaces and their great thickness making them impenetrable to direct impact of the heaviest shot. It is proposed to endeavor to introduce this device into the United States, where it is thought that it may be made even more successful, since our chilling irons are found to be superior to those of any other country. The turrets are usually of from 50 to 100 tons weight and are built up of great staves and segments, ten or fifteen of which constitute the low, wide, circular, covered box which constitutes the turret and protects the guns. The top is usually made of two semi-circular halves. In their manufacture, the quality of iron employed is presumably that found to make the best car wheels and one of peculiar strength and toughness, as well as of intensely hard chilling property. A *Grusonwork* is to be established at Chester, Pa., by New York and Philadelphia capitalists.

THE success of the submarine craft which have been recently produced in the United States and in France is stimulating other nations, and an authority among English technical journals—*Industries and Iron*—says: "In spite of the derision with which they have been received by our Admiralty, there is a prospect of submarine torpedo boats, becoming an important factor in the future strategy of marine warfare. Apart from the ancient history of diving or submarine torpedo boats, the recent activity, notably of the French and American naval authorities, and the favorable views with which the experts of these two nations look upon the latest developments in submarine torpedo boats, is more than ample justification for our Admiralty giving serious consideration to this most dangerous and constantly improving mode of torpedo attack. Our battleships are estimated to be worth £40,000,000 and our protected cruisers about £26,000,000, whilst other fighting ships of our Navy are valued at about £34,000,000, making in all a grand total of £100,000,000. Surely if our costly Navy is to be menaced with such a system of deadly torpedo attacks as may reasonably be anticipated from the modern submarine boats of foreign naval Powers, it behooves our Government to test and adopt counteracting means of attack, and also to endeavor to secure some more reliable means of defence against such attacks than at present obtain in our Navy.''

THE last year was the 'record year' for Great Britain as well as for the United States. That country registered a foreign trade totaling about four thousand dollars. The imports were £485,000,000, of £12 per capita of total population, the exports £264,000,000, about £6 // 11s, per capita and the re-exports £65, averaging £1 // 12s. There has never been a year in which so much trade was reported, so much manufacturing done or so much profit secured; notwithstanding the enormous amount of successful competition in the British market and the markets of the world, to which the United States and Germany have attained. Prosperity has been quite extraordinary in all manufacturing and exporting countries.

R. H. T.

BOTANICAL NOTES.

BOTANY AT WOODS HOLL.

FOR about a dozen years opportunities for botanical study have been offered to botanists at the Marine Biological Laboratory at Woods Holl, a seaside town on the southern coast of Massachusetts. Year by year the work offered has been enlarged, so that now, under the direction of Dr. B. M. Davis, of the University of Chicago, it includes a laboratory study of algæ, fungi, plant physiology, plant cytology and micro-technique, with lectures covering nearly the whole field of botany. The laboratories are open from July 5th to August 16th.

When we think of the poor preparation of so many of our teachers of botany in the high schools, and even the colleges and the so-called universities, it is strange that more of them do not take advantage of the opportunities offered by such a school as this at Woods Holl. It is encouraging to see that already eighteen colleges are coöperating in supporting this laboratory school. There should be many more of these. Every large institution should offer as a prize to its advanced men a room or table in the Woods Holl Laboratory. In many cases this would be of much more value to the recipient than a scholarship or fellowship costing the institution much more money. These might be called 'Woods Holl Scholarships,' the recipient to spend the season in work in the laboratory, and to bring back into his college at the end of the summer vacation the results of his studies.

MINNESOTA BOTANICAL STUDIES.

THE thick 'part' of this interesting and unique publication which appeared early in January, contains articles on *Chlorochytrium* (an endophytic alga of the Protococcaceae, found in the thallus of a marine seaweed), *Rhodymenia* (a red seaweed from the Pacific Coast), the Lichens of the Lake Superior Region (enumerating one hundred and fifty-eight species and varieties, forty-six of which had not hitherto been recorded from the interior flora of the United States), Lichens of the Minnesota Valley (enumerating two hundred and one species and varieties of which forty-one had not hitherto been recorded from Minnesota, one being new to science), Synonymic Conspectus of Native and Garden Aquilegias of North America (describing forty-six species and varieties), Synonymic Conspectus of the Native and Garden Aconitums of North America (describing seventeen species and varieties).

HARPER'S STUDIES IN CELL DIVISION.

THE December number of the Annals of Botany contains another of those valuable contributions to plant cytology which have appeared from time to time from the hand of Professor Harper. He takes up in the present paper the cell-division in sporangia and asci, using for the former mainly the species of *Saprolegnia* and *Achlya*, with some of the *Mucoraceae* and *Synchitriaceae*, also. For the cell-division of asci he has made use of his previous studies in the *Erysipheae*, and now adds *Lachnea scutellata* of the *Pezizaceae*. His summary of results is in part as follows:

"If we compare now the methods of spore-formation in the ascus and in the sporangia studied, the differences in the two cases are at once apparent. In the ascus, as in the higher plants, the cutting out of the daughter cell from the mother cell is effected by the agency of the same fibrous kinoplasmic elements as were concerned in the division of the nucleus. In the higher plants the flat cell-plate is formed by the 'cone-principal' of the karyokinetic figure as named by Van Beneden, while in the ascus the daughter cell is cut out of the protoplasm of the mother cell by an ellipsoidal cell plate formed from the fibers of the antipodal cone. In this process the daughter cell is cut out of the interior of the protoplasm of the mother cell, so that it remains surrounded on all sides by the material of the mother cell. The daughter cells do not contain all the protoplasm of the mother cell, a considerable mass remaining as the so-called epiplasm. This is typical free cell-formation, as I have pointed out before. In all the sporangia studied, the cleavage is from the surface of the protoplasm, or from the surface of vacuoles of the mother cell. The daughter cells are thus separated by cleavage-furrows, and the nature of the division from the surface inwards precludes the possibility of the formation of an epiplasm. * * *

"If we consider now the bearing of the observations presented, on the doctrine that the ascus is a more highly developed and specialized modification of the sporangium of the Zygomycetes, it is plain that the very different methods of cleavage in the two cases are opposed to the assumption of any close relationship between them. In fact, it seems rather difficult to imagine any intermediate stages which could connect the process of cleavage by surface-furrows, as seen in the sporangium, with the free cell-formation of the ascus. * * *

"The total dissimilarity of the process of cleavage in the sporangia described and the ascus as I have shown it in the above account, makes it necessary to look for the ancestors of the Ascomycetes elsewhere than in the lower Fungi. Thaxter's studies of the Laboulbeniaceae have emphasized greatly the resemblance of that group to the Florideae and the hypothesis of the multiple origin of the Fungi from the Algae has gained correspondingly in strength. * * *

"We can say, however, as noted above, that the unlikeness in the method of spore-formation in the ascus and the sporangia which I have studied, makes it impossible to assume any very direct relationship between the Phycomycetes and Ascomycetes."

SHORT NOTES.

COULTER and Rose contribute an important paper to the Proceedings of the Washington Academy of Sciences, consisting of a synopsis of Mexican and Central America Umbelliferae, in which all the data with respect to the umbelliferous flora of the region under consideration are brought together. Thirty-nine genera and one hundred and eighty-two species are enumerated.

AN interesting paper by O. Borge of Stockholm, on the fresh-water algae of Franz-Josefs-Land (Süsswasseralgen von Franz-Josefs-Land, Köngl. Vetens. Akad. Förhandl, 1899) enumerates the plants collected by the Jackson-Harmsworth Expedition. No less than forty-three species, representing twenty-two genera, are enumerated. These genera range from *Oscillatoria*, *Nostoc*, etc., to *Cosmarium*, *Spirogyra*, *Vaucheria* and *Oedogonium*. One new species is described, namely, *Monostroma fisheri*, of which, oddly enough, a variety, also (var. *minor*) was found.

C. G. LLOYD continues his 'Mycological Notes' (No. 4, November, 1899) and takes up the genus *Psalliota*, describing six species and varieties, and enumerating eighteen or twenty others which have been recorded as occurring in this country. Some of the latter are rare, some of doubtful occurrence, while others are based on erroneous determinations.

The report of the Botanist of the United States Department of Agriculture, recently issued, gives one some idea of the many kinds of work taken up by that division, including poisonous plants, seed testing, seed and plant introduction, economic plants of the tropics, etc.

Botanists may obtain a suggestion as to how to secure the publication of some of the matters they wish to distribute to the people, from a tiny pamphlet on the 'Stinking Smut of Wheat,' by Professor Bolley, of the North Dakota Agricultural College, which was 'published for the farmers of Minnesota and North Dakota' by one of the enterprising railway lines. It is popularly written, and at the same time is scientifically reliable.

Recent 'Contributions to the Flora of Queensland' by F. M. Bailey, Colonial Botanist, enumerate and describe many new plants, and call attention to certain plants 'reputed to be poisonous to stock.'

A recent report on the 'Timber Trees of the Herberton District of North Queensland,' by J. F. Bailey, assistant to the Colonial Botanist, is interesting to American botanists on account of the fact that but one of the genera enumerated (*Zanthoxylon*) is native to this country. One obtains little idea of the appearance of the Queensland forests from an examination of the descriptive list of one hundred and eleven names. What notion, for example, does one have of species of *Acronychia* and *Halfordia* (Rutaceae), or *Blepharocarya*, *Euroschinus* and *Pleiogynium* (Anacardiaceae), or *Aleurites*, *Baloghia* and *Mallotus* (Euphorbiaceae)?

The successive numbers of the *Forester*, 'a monthly magazine devoted to the care and use of forests and forest trees and to related subjects' contain so much that is botanical, and are so beautifully illustrated that we cannot do otherwise than commend it to botanists as a most helpful journal.

Charles E. Bessey.
The University of Nebraska.

SCIENTIFIC NOTES AND NEWS.

Sir Michael Foster has been returned to Parliament as representative of the University of London. The final vote was: Sir Michael Foster, 1271; Dr. Collins, 863; Dr. Busk, 586.

The Paris Academy of Sciences has elected as a corresponding member, Dr. H. G. Zeuthen, professor of mathematics at the University of Copenhagen.

Professor C. Barus, of Brown University, has been asked by the committee in charge to present a report on pyrometry at the International Congress of Physicists of the Paris Exposition.

Professor Ira Remsen, of Johns Hopkins University, will deliver the address at the dedication of the new chemistry building of the University of Kansas next fall.

The following named botanists and zoologists have recently joined the Washington Academy of Sciences as non-resident members: C. E. Bessey, University of Nebraska; John M. Coulter, University of Chicago; G. L. Goodale, Harvard University; C. S. Sargent, Arnold Arboretum; W. P. Wilson, Philadelphia Commercial Museums; W. B. Scott, Princeton University; Henry F. Osborn, Columbia University; David S. Jordan, Stanford University; William Brewster, Cambridge, Mass.; J. A. Allen, American Museum of Natural History; E. A. Andrews, Johns Hopkins University; H. C. Bumpus, Brown University; Carl H. Eigenmann, Indiana University; Walter Faxon, Harvard University; Chas. H. Fernald, Mass. Agricultural College, S. A. Forbes, University of Illinois; Simon H. Gage, Cornell University; Samuel Garman, Museum of Comparative Zoology, Cambridge; Alpheus Hyatt, Boston Society of Natural History; C. C. Nutting, State University of Iowa; Arnold E. Ortmann, Princeton University; W. E. Ritter, University of California; R. E. C. Stearns, Los Angeles, California; R. P. Whitfield, American Museum of Natural History; Edmund B. Wilson, Columbia University.

As we have already announced, Professor R. W. Wood, of the University of Wisconsin, is at present in England, having been invited by the Society of Arts to lecture on 'The Method of

Color Photography by Means of Diffraction Gratings,' which he has described in this JOURNAL. This lecture was announced for February 14th. Professor Wood was invited while in London to lecture before the Royal Society on February 15th, his subject being 'Photographs of Sound Waves and the Kinematographic Demonstration of the Evolution of Reflected Wave Fronts,' and before the Physical Society on February 23d, on these and several of his other recent discoveries in physics. He has also been invited to lecture before the Royal Photographic Society and the Camera Club.

WE learn from the *Botanical Gazette* that Dr. Douglass A. Campbell, professor of botany, in Leland Stanford University, has been spending some time in the University of Berlin and is at present in Egypt.

THE Prussian Ministry of State has expelled Dr. Arons, docent in physics at the University of Berlin. It will be remembered that charges were brought against Dr. Arons for advocating the doctrines of social democratic party and that the University Senate refused to discipline him.

WE regret to record the death of President James H. Smart of Purdue University, Lafayette, Ind.

THE death is announced of Professor Charles Piazzi Smyth, the astronomer. He was the son of Admiral William Henry Smyth, a well known hydrographer and astronomer, and was born at Naples in 1819. He began his astronomical work at the Cape of Good Hope in 1835 and was appointed Astronomer Royal of Scotland and Director of the University of Edinburgh in 1885. He is best known to the general public for his publications on the 'Great Pyramid.'

THE death is also announced of Mr. Leander J. McCormick who founded the observatory at the University of Virginia which bears his name.

THE Royal Institution, London, has received for the promotion of experimental research at low temperatures, £100 from Sir Andrew Noble. The Institution has also received £100 from Mr. Charles Hawksley, and £25 from Mr. Frank McClean.

EX-REPRESENTATIVE Isaac Stephenson of Marinette, Wis., has announced his intention to give to that city a public library building, to cost $50,000.

ON the evening of February 21st, the Trustees of the Corcoran Gallery of Art, at Washington, D. C., gave a reception to the Washington Academy of Sciences and their guests, the American Institute of Mining Engineers. The spacious halls of the gallery were thrown open and a considerable assemblage was present notwithstanding a very stormy evening.

THE following delegates representing scientific organizations, have been assigned from the District of Columbia to attend the Pure Food and Drug Congress: *District of Columbia Chemical Society:* Professor W. H. Seaman, W. H. Krug, Professor Charles L. Reese, W. E. Patrick, J. K. Haywood, A. L. Brown; *Department of Agriculture:* Secretary James Wilson, Dr. D. E. Salmon, Dr. H. W. Wiley, William Saunders, Mr. W. N. Irvin, J. H. Brigham, Dr. W. D. Bigelow; *Army Medical Department:* Lieut.-Col. Charles Smart, Dr. William M. Mew; *Navy Medical Department:* Medical Director, Charles H. White; *Health Department District of Columbia:* Dr. Wm. C. Woodward, Professor J. D. Hird, Mr. H. C. McLean, Dr. W. C. Fowler; *American Pomological Society:* Professor Wm. A. Taylor; *Commissioners of Pharmacy:* Dr. John T. Winter, Dr. W. P. Carr, G. G. C. Simms; *Pharmaceutical Association:* W. G. Duckett, H. A. Johnston, R. M. Harper; *College of Pharmacy:* W. S. Thompson, F. M. Criswell, S. T. Hilton.

THE preliminary announcement has been issued for an International Congress of General Botany to be held at Paris from the 1st to the 10th of October of the present year. The official language of the Congress will be French, but papers in other languages will be accepted if they are accompanied by a brief abstract in French. Abstracts must be received not later than September 16th. The president of Congress is M. Prillieux, and the secretary, M. Perrot, École Supérieure de Pharmacie, Paris.

AN International Congress of Navigation will be held at Paris from July 28th to August 3d. It will include in its scope not only navigation of the sea, but also the navigation of rivers and canals.

THE House Committee of Mines and Mining has acted favorably on a bill creating a department of mines and mining, with a cabinet minister. The Geological Survey would be transferred to this department. There is also, as we have also reported, a bill before Congress establishing a department of Commerce and Manufactures, to which it is proposed to transfer the U. S. Geological Survey, as well as the U. S. Coast and Geodetic Survey, the Patent Office, the Commission of Fish and Fisheries, and the Bureau of Navigation. The Treasury Bureau of Statistics and the Bureau of Foreign Commerce of the State Department are to be consolidated into a single bureau of the department. The principal new offices created are the secretary and assistant secretary of commerce and industries, the secretary receiving a salary of $8000 and the assistant secretary $4000.

THE Ontario government has completed arrangements for the formation of a forest of almost 3000 square miles, embracing the district in which Lakes Temagami and Lady Evelyn are situated. The bulk of the reserve is virgin forest, with the finest white pine in Canada upon it.

THERE were 533 deaths from the plague in Bombay during the week ending February 16th. Up to February 17th there have been 42 cases of the plague and 32 deaths at Manila. The influenza is seriously epidemic throughout Europe and has been increasing during the past two weeks in New York and other cities.

FOR the accommodations of those who wish to view the eclipse of the sun, which takes place on May 28th, Messrs. Cook have arranged a conducted tour, leaving London, May 21st, visiting Paris, Bordeaux, Biarritz, Madrid and Talavera, where the total phase of the eclipse will be visible.

A TELEGRAM has been received at the Harvard College Observatory from Professor Kreutz, at Kiel Observatory, stating that "Comet *a* was observed by Javelle at Nice, Feb. $17.^d3148$ Greenwich Mean Time, in R. A. $2^h\ 22^m\ 2^s.8$ and Dec. $-1°\ 19'\ 27''$." The check word shows that there is an error in this telegram, although it has been correctly repeated from Kiel. A cablegram, asking information, was sent to Professor Kreutz, but no reply has yet been received. If we assume an error of 10° in the addition, the message will check. The observation can not have been made on February 18th.

THE thirty-fifth volume of the *Zoological Record* has come to hand. Although chiefly relating to the year 1898, it includes the literature of the Coelenterata for 1897 and 1898. Copies may be obtained of the Secretary of the Zoological Society of London. Price, 30 shillings.

A NEW edition—the second—of 'Recent and Coming Eclipses' by Sir Norman Lockyer is now ready. It contains an account of the observations made at Viziadarog, in India, in 1898, and of the conditions of the eclipses visible in 1900, 1901 and 1905.

THE Duke of Devonshire and the President of the Board of Trade received, on February 5th, a deputation which presented a memorial asking for the continued maintenance of the Buckland Museum of Economic Fish Culture. The memorial stated, as we learn from the London *Times*, that the late Frank Buckland, who was appointed one of her Majesty's Inspectors of Fisheries in 1866, formed the museum at his own expense to aid the practical study of fish and fisheries and to teach people, through the eye, their practical value. He cast for it, mostly with his own hands, 400 specimens of fish, and collected a large number of objects illustrating fish and oyster cultivation and preservation and the modes of taking fish. This museum he bequeathed to the nation on trust to form part of the national collection at South Kensington Museum, and he also bequeathed £5,000, after his widow's death, to found a professorship of economic fish culture in connection with the museum. The gift and its conditions were formally accepted by the Department of Science and Art in 1881; but in 1898 the Select Committee appointed to inquire into and report upon the administration and cost of the museums of the Science and Art Department recommended that the Museum of Fish Culture should be abolished. The memorialists offer various reasons why this recommendation ought not to be sanctioned. Among other things they recall the fact that at the closing ceremony of the Fisheries Exhibition of 1883 the Prince of Wales said: "I think our duty towards the supporters of the exhibition will not be discharged until we have done something towards the promotion of that application of science to practice from which the fishing industry, like all other industries, can alone look for improvements." The Prince proposed the formation of a society having for its objects the collection of statistics and other information relative to fisheries, the diffusion among the fishing population of a knowledge of all improvements in the methods and appliances of their calling, the discussion of questions bearing upon fishing interests, and the elucidation of those problems of natural history which bear upon the subject. To extend the usefulness of the museum on these lines, and also on lines suggested by Professor Huxley, the coöperation of the Board of Trade appears to the memorialists to be essential. They suggest various directions in which such coöperation could be usefully afforded by inspectors of fisheries and others, and they submit that to disperse or neglect the museum would be a retrograde step unworthy of a great maritime country, a breach of an engagement of the Government, and an injustice to the memory of an able public servant. They ask that the museum shall be maintained and exhibited at South Kensington permanently and in a proper and efficient manner in accordance with the terms of the bequest accepted by the Department of Science and Art, and that such steps may be taken, in accordance with the suggestions of the Prince of Wales, as may be deemed expedient for securing its permanent usefulness in the interests of the river and sea fisheries of the United Kingdom. The memorial is signed by the Dukes of Richmond, Bedford, Northumberland, Sutherland, Westminster, and Abercorn, the Marquises of Tweeddale, Bute, Dufferin, Worcester, and Granby, the Earls of Home, Stamford, Sandwich, Jersey, Portsmouth, Radnor, Kimberley, and March, Lord George Hamilton, Viscount Powerscourt, Viscount Folkestone, Lords Massy, Chelmsford, Tweedmouth, and St. Levan, Lord Justice A. L. Smith, Sir William Harcourt, Sir Edward Birkbeck, together with representatives of the Fishmongers' Company, of various fishery boards and angling societies, inspectors of fisheries, and many others.

UNIVERSITY AND EDUCATIONAL NEWS.

INSTRUCTION IN ARCHÆOLOGY AND ETHNOLOGY IN THE UNIVERSITY OF PENNSYLVANIA.

DR. DANIEL G. BRINTON, for thirteen years Professor of American Archæology and Languages in the University of Pennsylvania, died July 30, 1899. His death was more than a great loss to the University—it was in a sense an irreparable loss. He had long been recognized as foremost among the students of the aboriginal languages of North America, and in that branch of research no one could be found to take his place. Dr. Brinton himself, however, shortly before his death, took steps towards ensuring in the University the permanence of the work to which he had devoted himself. He presented to the institution his library of works relating to the aboriginal languages of North America, comprising about 3000 volumes and embracing a large number of unpublished manuscripts as well as nearly all the printed material now extant. He had also recommended the appointment of his friend and co-worker, Mr. Stewart Culin, as Lecturer in Ethnology and American Archæology, and shortly after his death Mr. Culin was named for that position by the authorities of the Graduate School and was appointed by the Board of Trustees.

Mr. Culin has long been connected with the Museums of the University, and is now the curator of the Section of Asia, and General Ethnology. He is the author of between twenty and thirty published papers and monographs, and is best known by his work on Games. He was the first to show definitely that the games of all civilized races are descended from certain divinatory practices, many of which still exist among primitive peoples with their original significance unobscured.

During the year 1900–1901 Mr. Culin will offer courses upon the outlines of American

Archæology and upon Comparative Ethnology. In order to systematize still further the work offered in Archæology, Dr. Hillprecht, Professor of Semitic Philology and Archæology; Dr. Clay, Lecturer in Assyrian, Hebrew and Semitic Archæology, and Dr. Bates, Lecturer in Greek and Classical Archæology, have been associated with Mr. Culin in the administrative group entitled Archæology and Ethnology, and will offer courses next year in Babylonian and Early Hebrew and Phenecian Paleography. The Life and Customs of the Early Babylonians, Hebrew Archæology, Greek Epigraphy and Greek inscriptions.

It is the intention of the University to develop the work in Archæology and Ethnology in connection with the Free Museum of Science and Art. The collections now in the Museum offer students of Early Babylonian Archæology opportunities unrivalled in America, and in some respects unexcelled in the world. The material relating to the primitive culture of North America and of Borneo is also very rich, and that relating to Egyptian and Classical Archæology is sufficient to render substantial aid to instructors in those departments.

GENERAL.

President Gilman of Johns Hopkins University has made a plea before the finance committee of the Maryland Senate for a renewed State appropriation of $50,000 annually for two years. After enumerating the losses sustained by the university in the depreciation of Baltimore and Ohio Railroad stock values and the suspension of dividends, he said: The expense of maintaining the university is not far from $200,000 a year. The income from investments is $100,000. The income from tuition, $50,000. These are all round numbers, varying a little year by year. Unless the deficit of $50,000 can be made up, contraction must follow. Contraction will bring great discredit, for it will be known throughout the land. Students will drop out and a period of anxiety will follow. The university has no debts. Its capital invested in land, buildings, books and apparatus, is $1,000,000. It has excellent friends, wide reputation, and the hopeful prospects of large gifts. But it cannot anticipate the legacies which are known to be drawn in its favor. What is needed is a continuance of the aid which the last Legislature gave for two years more.

The condition of affairs at the University of Cincinnati is extremely unfortunate. The University occupies a somewhat peculiar position being a municipal institution with its Board of Directors appointed by the Superior Court of Cincinnati. It was founded by a citizen of the city with a considerable endowment and has received gifts from other citizens; but it has received its site and central building from the city and obtains three-tenths of a mill from the city tax list. It is regarded as the head of the public educational system of Cincinnati and the students are nearly all from the city. The experiment of a municipal university is certainly interesting and it is unfortunate that its future is at present endangered by political and personal factions. The condition of affairs has already been briefly reported in this Journal. Of the twelve members of the academic faculty, eight have been compelled to withdraw, no definite charges having been made. Several of them are men of science with established reputation. Of the four remaining professors one has resigned as a protest against the action of the Directors. He has published an open letter condemning in very outspoken language the action of the president. At a meeting of the Board of Directors on February 19th, a committee of citizens presented a protest, but the Board refused to give the Faculty a hearing.

Mr. James Russell Parsons, Jr., has been elected Secretary of the University of the State of New York.

Dr. Wilhelm Wien, professor of physics at Giessen, has been called to Würzburg as successor to Professor Röntgen.

Dr. Stanislaus Ciechanowski has been appointed assistant professor in the University of Crakow, and Professor v. Hertling, of Munich, has been called to the professorship of philosophy at Bonn, in the place of the late Dr. Neuhäuser.

Dr. E. Ashkinass has qualified as docent for physics in the University of Berlin, and Dr. U. Belu for physics and Dr. Reitter for chemistry in the University of Bonn.

SCIENCE

FRIDAY, MARCH 9, 1900.

CONTENTS:

MSS. intended for publication and books, etc., intended for review should be sent to the responsible editor, Professor, J. McKeen Cattell, Garrison-on-Hudson, N. Y.

PROFESSOR THOMAS EGLESTON.

THOMAS EGLESTON, planner and first professor of the School of Mines of Columbia University, died on Monday morning, January 15th, at his home, 35 West Washington Square, New York City, at the age of sixty-seven years.

Professor Egleston was born in New York City, December 9, 1832. He prepared for college under Dr. Dudley, of Northampton, took the regular four years' classical course at Yale and graduated in 1854; and in the following year took a post graduate course in the Yale Scientific School of Analytical Chemistry under Professor Benjamin Silliman, Jr.

In 1856 he went to Europe more for rest than to pursue any special course of study, but, becoming interested in the lectures in geology and chemistry at the Jardin des Plantes of Paris, he spent a good deal of time in the collections and laboratories and later, desiring to pursue more systematic work, applied for and obtained the permission of the government to attend certain lectures at the École des Mines, especially those of Professor de Senarmont on Mineralogy, of Elie de Beaumont on Geology, and of Professor Bayle on Paleontology. He completed his course at the school in 1860, having not only attended the lectures but worked in all the laboratories. During the vacations and at the close of his course he travelled extensively in France and Germany, studying and collecting.

In 1861 Mr. Egleston returned to New York city and was at once chosen by the Smithsonian Institution at Washington to take charge of the work of sorting and arranging the specimens of minerals and rocks which had accumulated as a result of various exploring expeditions. To facilitate the work and assist in the system of international exchanges then undertaken, he prepared a check list of minerals with their compositions, which was published by the Institution.

At this time the need for a school of mines and metallurgy in this country was beginning to be recognized. Schools of civil engineering existed and schools of science, but nothing especially devoted to mining or metallurgy. Mining operations were conducted by so called 'practical miners,' with here and there a graduate of a foreign school, and the waste and mismanagement were almost beyond belief.

The nearest previous approach to the formation of such a school is found in the incorporation in New York State, about 1859, of the 'American School of Mines' with the avowed object of "The economic and scientific development of the mineral wealth of the United States, the determination of its economic values, instruction in the art of practical mining and the analysis and composition of mineral products." This institution does not appear ever to have reached a stage of active existence.

Dr. Egleston prepared and published in March, 1863, a 'Proposed Plan for a School of Mines and Metallurgy in New York City,' which was simple and practical and founded undoubtedly upon the methods pursued at the École des Mines. In about 1500 words he stated the object of the school, the proposed course of instruction, and the estimated cost of establishment.

The object stated was "To furnish to the student the means of acquiring a thorough scientific and practical knowledge of those branches of science which relate to mining and the working up of the mineral resources of this country, and to supply to those engaged in mining and metallurgical operations, persons competent to take charge of new or old works and to conduct them on thoroughly scientific principles." A course of three years was outlined which was closely adhered to for the first few years of the school and then gradually modified. The estimated cost of equipment was $17,300, of which over half was for collections.

Dr. Egleston's idea appears to have been to graft the school upon some existing institution, and fortunately he submitted the plan to the Trustees of Columbia College, who for four or five years had been considering the extension of the work of the college by the establishment of graduate schools, among others a 'practical school of science.' The opportunity to make a first step in this direction seemed to exist in the plan of Dr. Egleston, for it was proposed to pay all expenses of the school from the fees, and while the organization as planned required a larger outlay than the financial condition of the college warranted, the committee of the Trustees reported that, "the nucleus of such a school could be formed at inconsiderable cost to the college and so as to be capable of expansion whenever the means of the college shall permit." The Trustees, thereupon set apart rooms in the college building for mineralogical and geological collections, appropriated $500, for fitting up cases and, on February 1, 1864, appointed Thomas Egleston, Jr., Professor of Mineralogy and Metallurgy without salary.

Although no money was appropriated with which to buy collections of minerals or rocks, the small collection of the college was placed at the disposal of the new school, and Dr. Egleston obtained gifts from Mr. George T. Strong and the Hon. Gouverneur Kemble, with which two private collections of considerable value were purchased. From these, before the opening of the school, he formed a very fair working collection of minerals and a smaller geological collection.

An assay room, with a furnace for every four students, and a chemical laboratory were fitted up in one of the cellars. As one of the first students writes: "Though the actual state of these necessary aids to study was not good, the collections were all planned on a great scale and as far as possible the work was done thoroughly. The assay laboratory was the best in the country, the crystal models for every day use more abundant and complete than in any other school in the world. The best design was sought in tables and cabinets, and with all its shortcomings the new institution not only gave full promise of its present state of perfection, but was in fact superior in some respects to any existing at the time."

On November 15, 1864, the school opened with fifteen students, which by the end of the month had risen to twenty-nine and a little later to forty-three, the list including graduates of common schools and colleges, business men and civil engineers in full practice.

Early in 1865 the trustees recognized the success of the experiment and definitely made the School of Mines a coördinate branch of Columbia College. It has steadily developed, widening by the addition of courses in civil engineering, chemistry, architecture, electrical engineering, sanitary engineering and mechanical engineering into the existing cluster of schools in applied science under one faculty, with 1300 graduates and over 2000 others who have attended partial or special courses.

In the first four years of the School of Mines Dr. Egleston devoted himself to the preparation of lectures in mineralogy and metallurgy, to the accumulating and bringing into shape the mineralogical collection and to the preparation of needed text-books. All his publications prior to 1872, with the exception of a report upon a 'geological and Agricultural Survey of the first hundred miles of the Union Pacific Railroad,' which he conducted in 1866, were text-books, tables and catalogues for the use of students of the School of Mines. It is noteworthy that while Dr. Egleston's first love was mineralogy and, as he expressed it, he "only took charge of metallurgy because at the time he could not persuade anyone else to take it," yet after the completion of his text-books in mineralogy he did little or no work in this direction, except in the development of the collection. In the collection work he never relaxed and even the year of his retirement, when grievously broken in health, insisted on personally choosing and setting in the new specimens.

In metallurgy, on the contrary, he published nearly one hundred books and papers, covering a wide field and to a very great extent the result of data collected in his yearly trips to different parts of the world. This complete passing into metallurgy was practically coincident with and in a measure caused by the founding of the American Institute of Mining Engineers in 1871. Dr. Egleston was approved for membership at the first meeting and thereafter for over twenty years was one of its most vigorous members, twice a manager, three times vice-president, and in 1887 president. He contributed to their transactions over thirty articles, and in this same period he published over twenty articles, principally metallurgical, in the *School of Mines Quarterly*, and contributed also papers to the American Society of Civil Engineers and American Society of Mechanical Engineers, The New York Academy of Sciences, and in the *London Engineering* he published a long series of articles upon the Metallurgy of Silver, Gold and Mercury in the United States, which, with other matter, were reprinted in two large volumes in 1887 and 1890, and constitute his most ambitious work.

Aside from his scientific work, Dr. Egleston took a very active part in religious and charitable work. He was a vestryman of Trinity Church for twenty years, and at the time of his death was Junior Warden, as well as member of several committees. For nearly thirty years he was Vice-President of the Protestant Episcopal Mission Society and a Trustee of the General Theological Seminary. He is also to be credited with the establishment of 'Food Kitchens' in New York, and with organizing the Public Parks Association by which Washington Square was saved. The Audubon Monument movement was also started by him.

In 1874 Princeton conferred upon him the degree of Ph.D., and Trinity that of LL.D. In 1890 he was appointed a Chevalier of the Legion of Honor by the French government on the recommendation of the Director and members of the Faculty of the École des Mines. In 1895 he was made 'Officier.' It is pleasant to record also that since his death the Trustees of Columbia University have named the Museum of Mineralogy the 'Egleston Mineralogical Museum,' thus attaching his name permanently to the collection which he created and loved.

In 1896 his health gave way, and though after a rest he endeavored to resume his work, he could not stand the strain and was retired June 30, 1897, at his own request, as Professor Emeritus.

The service of Dr. Egleston to science lies not so much in his numerous writings, though these contain an enormous mass of valuable information collected with infinite labor and published always when and where they were needed. Far more important was what has been happily called 'his intuitive perception of the situation,' his recognition of when the time was ripe to inaugurate a movement, his skill in organization and the amazing vigor, persistency and unfailing belief with which he forced it to success.

Alfred J. Moses.

THE SEVENTIETH BIRTHDAY OF CARL VON KUPFFER.—HIS LIFE AND WORKS.

Professor von Kupffer has lately passed the mark of three score years and ten and has received the congratulations of his students of many lands. Some of these, following the good German custom, have prepared memoirs in his honor which appear in a memorial volume and were presented him as a birthday gift. Von Kupffer has been a most helpful friend to the Americans who have carried on their investigations in the Anatomical Institute in Munich during the past generation, and it seems but just that at this time an American journal should pay a tribute to his life and work.—Editor of Science.

Carl von Kupffer ranks to-day as one who has taken a place within the innermost circle of comparative embryologists. He has long been recognized as a profound scholar in a broad field of zoological knowledge; he is best known, however, for his researches upon the structure, development and descent of the vertebrates.

In his biography von Kupffer presents an interesting parallel with the great embryologist, Karl Ernst von Baer. Both were natives of the Baltic provinces of Russia, students and graduates of the University of Dorpat, and sometime practicing physicians until drawn into zootomical-embryological research. Both were for a time professors at Königsberg, and showed a distinct bent towards the widely separate themes of Arctic exploration and craniology; they were equally interested in matters relating to fish and fishery and contributed important memoirs to this subject. On the other hand they had in general but little leaning towards work of the systematst.

Both left Königsberg for wider fields, von Baer, however, to largely lay aside his embryological researches, the other to extend and correlate his. An interesting difference between the two embryologists is this, that von Baer had completed his most important work when he was scarcely over forty years of age, while von Kupffer had not begun his best known work until he was over sixty. A further difference is that Kupffer has held fast to the early themes of his research. Von Baer lived until his eighty-sixth year; von Kupffer has entered his eighth decade with every prospect of many years of active work.

Von Kupffer has devoted forty-five years to his researches. And these he has embodied in upwards of fifty memoirs. The number seems relatively small—the bibliography of von Baer is six times as great—but this is explained by the fact that the papers are mainly of a critical character and are the fruit of intricate and time-consuming studies, just as von Baer's 'Entwicklungsgeschichte der Thiere' was the outcome of no less than nine years' of assiduous labor.

The writings of von Kupffer deal in the main with problems in special fields of embryology. A number of his well-known papers are contributions to histology, and there are several dealing with craniology, including the memoirs on the skull of his illustrious predecessor in Königsberg, Immanuel Kant.

The histological work of von Kupffer extends over a wide range of subjects. To cytologists he is known as a pioneer in the study of the ultimate nature of protoplasm. Thus, according to Bütschli, he ranks as the first to demonstrate satisfactorily the reticulo-vesicular character of protoplasm in living tissue. His observations in 1870 in the follicle cells of Ascidia showed distinctly the reticular meshwork and the breaking up of the cytoplasm into ultimate 'vesicles.' He also indicated for the first time (1870) the radial arrangement of the alveoli around the nucleus, together with the 'marginal alveolar layer.' The term 'paraplasm' used by von Kupffer in 1875, is still in use (as the equivalent of what at present is more often known as 'metaplasm') although in a somewhat different sense than that in which it was first used. His sustained interest in this theme was lately shown in his inaugural address (1896) as rector of the University of Munich.

The processes of the fertilization of the egg have been described by him in several forms. In an early paper on this subject he expressed his belief that in large meroblastic eggs a process of physiological polyspermy occurs, a view which his student, Professor Rückert, and other investigators have since confirmed and extended. His studies on fertilization have thus been important as leading the way for other papers from his laboratory—such for example as those on the fertilization of the lamprey and of the teleost by his devoted friend, Dr. A. A. Böhm, and also the earlier work of Theodor Boveri.

Von Kupffer's work should next be noted in connection with the structure of glands. In his studies on the histology of the liver he proved the presence of the secreting vacuoles in the gland cells and of the intralobular fibrous sheath. He next discovered the remarkable Sternzellen (or 'Kupffer's cells') in the wall of the portal capillaries: these he showed were not nervous, as was at first believed, but highly modified endothelial cells, and later he demonstrated their function as phagocytes. His researches on the development of the mammalian kidney should here be mentioned: these he carried on by means of serial sections cut by free hand—this was long before the time when section cutting became general—and by this means he was able to demonstrate more satisfactorily than had hitherto been done the early separation of the mesonephric from the metanephric kidney, and he first showed the essential relations of the permanent kidney and its ureter to the mesonephric duct.

Another of his histological works deals with the structure of the stomach, in this in a measure preparing a way for the exhaustive comparative studies of his student, Professor Oppel. Other contributions relate to the development of the liver, spleen and pancreas (in *Ammocoetes*) and afford striking evidence that these organs are closely related genetically. Further papers discuss the characters of muscle cells, and the origin of blood in the valves in the dorsal vessel of the leech (*Rhynchobdella*). In his earlier work he was also attracted into the puzzling field of the electric organs in fishes (*Gymnotus*, *Mormyrus* and *Malapterurus*).

Another and perhaps the most important line of his histological work relates to the structure of nerves. He thus demonstrated that the axis cylinder was not a solid structure in the sense of the earlier investigators. This condition he showed was artifact: the 'cylinder' is rather to be looked upon as an axial canal containing in its fluid contents the delicate fibrils. In the matter of the central origin of nerve fibers his further observations have yielded a basis of the new neurone theory. The difficult question as to the exact mode of termination of nerve cells in an end-organ he also successfully answered in one of his earlier papers; in the salivary gland (*Blatta*) he was able to trace the final arborescence of the nerve filaments on the wall of the gland cell and he described the discoidal enlargement at the tip of each fibril.

Von Kupffer had never played the rôle of a pioneer in any extended field of embryological research. He has done the work—which has only too often the greater value—of extending, correcting and interpreting the results of earlier observers. Thus his famous work on the development of the Ascidian was in the path which had been opened by Kowalewsky, whose results, as von Kupffer himself notes, were then almost universally discredited. Von Kupffer soon came to support the new cause and he even outdid Kowalewsky himself in advocating the closer affinities of the ascidians and chordates. He thus showed in the ascidian the continuity of the cord and brain, the 'segmentation' of the tail, the presence of 'spinal nerves,' and the distinctly chordate character of the notochord, together, later, with interesting homologies in the sense organs. And so too in his extended paper on the development of the Lamprey he took up the unfinished work, and succeeded in reconciling several discrepancies in the results of Max. Schultze and Shipley. But it should be understood that the results of pioneer investigators were to von Kupffer but as the foundation stones of detailed and original work. Thus in his paper on the lamprey he soon laid aside his purely critical studies and attacked a series of difficult problems relating to the origin of the mouth, the cranial nerves, and of the primitive conditions of the central nervous system.

Gastrulation is one of the most difficult processes with which the student of the development of vertebrates has to deal. And it is upon this theme that the work of von Kupffer has thrown no little light. It was formerly thought—and this was the rock which wrecked the results of Pander, Baer, and Rathke—that in the large yolk-filled eggs of such animals as reptiles and birds the germ-layers of the embryo arise one from the other by a process of splitting (delamination). Von Kupffer, however, was able to demonstrate that in these forms a process of infolding occurs, modified, it is true, but proving that the gastrulation of the higher forms is clearly homologous with that of the amphibia and many fishes.

He was also the first to give a satisfactory interpretation to a characteristic structure of the gastrulation of the meroblastic types, the primitive streak. An especially remarkable feature of von Kupffer's work was that he made his interpretation of the invaginate character of the early gastrula of a meroblastic type in his study of the teleost—a form in which the appearance of the infolding process is so difficult to observe that his early results were for thirty years discredited—and it is only recently that the 'prostoma' in these forms is again described (Sumner). It was his earliest paper on teleostean development, by the way (Ref. No. 6, II.), which describes 'Kupffer's vesicle,' which in the matters of its homology and function has since been an unusually fruitful theme for controversy. We may note in passing that von Kupffer believed that the region of the prostoma was (as he also interpreted the primitive streak of amniotes) the *only* region of gastrulation in the bony-fish, that he failed to determine the invaginate character of the germ ring, and that he interpreted the early embryo as equivalent to the primitive streak, and not therefore to the actual embryo.

In connection with Kupffer's work on the development of the teleosts it should be mentioned that it is he who deserves the credit for the view that the cells of the blastoderm are the progenitors of the periblast nuclei, and that they also give rise to the tissue cells of the embryo, questions of great theoretical importance. His work on the development of the herring, undertaken in the interest of the Commission for the Investigation of the Fisheries of the German Ocean, is a further memorable contribution to the biology of fishes. Here for the first time in any extended embryological memoir photo-micrographs were introduced as plates.

Only a tithe of von Kupffer's publications relate to the development of mammals. His most noteworthy paper deals with the question of the 'inversion of the germ layers' which had been described in a rodents, a condition which appeared to be an extraordinary contradiction to the usual mode of origin of the germ layers. By means of a series of stages of the field-mouse he showed conclusively, however, that this 'inversion' was only apparent: during early growth the embryonic area bowed downward to the ventral side of the ovum, so that the flattened gut came to be apposed to the surface while the central nervous system was left to develop within the cavity of the ovum.

The philosophy of the vertebrate head has furnished the fruitful theme of von Kupffer's studies during the past ten years. And his memoirs (three of the series have thus far appeared) upon this subject are, I think, regarded generally as his *magnum opus*. His endeavor in these memoirs is to demonstrate by ontogenetic conditions in the lowest craniotes the mode of origin, phylogenetic, of the structures of the vertebrate head—brain, cranial nerves, sense organs, mouth region, muscles and skeleton. The plan of this series accordingly recalls somewhat that of Dohrn in his 'Urgeschichte der Wirbeltiere,' although the views of their authors are usually widely at variance. Von Kupffer derives the ground plan of the conditions of the vertebrate head from that in the protochordates while Dohrn, for a long time, at least, has been the strong supporter of the famous annelid theory. Certain it is that the results of von Kupffer are welcomed by the warmest interest even by those whose faith in the great value of developmental characters as tests of phylogeny has been severely shaken. And all will admit he has already been able to clear up a number of doubtful points in cranial problems: thus, to mention but an instance or two of the general value of his work, it is now found possible to determine definitely the most anterior point of the brain and to compare with certainty—thanks to his revision of topography—such widely distinct and important regions as those of the lobus olfactorius impar, the recessus opticus and the tuberculum posterius, in all chordates from amphioxus to man. So, too, his determination of the metameral characters and subdivisions of the cranial nerves bids fair to become a classic if not an epoch-making contribution to the philosophical side of this long investgated and difficult subject.

In a late number of the Münchener Medicinische Wochenschrift, Professor Rückert* pays a tribute to von Kupffer's remarkable power of continuing and improving the quality of his work in spite of the burden of seventy years, and he concludes his paper with the wish that von Kupffer will long be spared to continue his good work. In this wish his American colleagues heartily join.

Bashford Dean.

The following bibliography of von Kupffer is largely due to the kindness of my friend, Dr. L. Neumeyer, of the Anatomical Institute in Munich.

RECENT PROGRESS IN GEODESY.*

This report is not based upon a complete examination of the recent literature of geodesy. The writer has been too busy to devote much time to the special research necessary to justify any claim to completeness. His regular duties have, however, kept him in touch with recent operations in geodesy, much more closely in touch, however, with operations in the United States than with those of Europe. The sketches of recent progress in each of several sciences called for by the rules of the Society are, as I conceive, to be written primarily, not for those well versed in that particular

*Forming a part of the Report of the Standing Committee on Mathematical Science for 1899. (Read before the Philosophical Society of Washington, February 3, 1900.)

science, but for the general information of others working on other lines. To this end a bird's-eye view of the present state of the particular science, together with a statement of the more important and interesting recent developments, will serve better than a detailed catalogue of the separate steps which make up recent progress.

By studying the recent reports of the International Geodetic Association and the geodetic reports from various countries, one is gradually convinced that there is well-sustained activity in geodetic operations in many countries, that geodetic facts are being steadily accumulated, and that steady progress is being made in improving methods and instruments. Having realized this, one naturally looks for published collections of results, and for some reasonably complete and well-digested scientific papers showing the relation between existing theories and results. One expects to find a considerable portion of the accumulated facts published in convenient form for the use of the hydrographer, topographer, the physicist, and the engineer. But this expectation is not realized. Of the great store of accumulated facts only a small part are as yet published in any complete or systematic way. The remaining ones are published, if at all, in such a fragmentary and disconnected form as to lose much of the value which they would otherwise have. Again, one looks in vain for any comprehensive study in recent years of the earth's figure and size. Since the publication by Colonel Clarke, some twenty years ago, of his values for the polar and equatorial radii, no corresponding comprehensive investigation has appeared in print.

It is not easy to understand why publication and discussion should lag so far behind the measures in the field. One consideration presents itself, however, as a partial, though insufficient, explanation. To adjust a network of triangulation requires an amount of expert computing which, as to time and cost, seems disproportionate to the field-work. Consequently, there is a decided tendency for the computations to be several years behind the corresponding field operations. By the time computations are finished for a given area new results of observations are available in that area or in adjacent connecting areas. Thus it always seems that the time for publication has not come, since whatever might be published would of necessity be incomplete.

It may be admitted that in many cases the computations made have been more complex and laborious than was warranted by the observations. The problem is one which lends itself to many theoretic refinements leading to long computations.

In what is above written as to delays in publication and computations needlessly prolix the writer must not be understood as referring chiefly to work in United States. Publication is apparently no further behind in this country than in other countries, with the possible exception of Great Britain. In simplifying the computations in office to correspond with the accuracy attained in the field, this country is easily foremost.

The years 1898 and 1899 mark an epoch in the history of geodesy in the United States. In 1898 the last of the field operations on the great transcontinental arc, extending from the Atlantic to the Pacific along the thirty-ninth parallel, were completed. During the same year the field measures of the oblique arc parallel to the Atlantic coast were also completed. In 1899 the necessary observations to complete an oblique arc in California, extending from Point Arena to the Mexican boundary, were brought to a close. In 1899 also, but little more than a year after the completion of the last field measurements, the computations connected with the arc of the thirty-ninth parallel were completed and the results put in form for the printer.

To appreciate the full force of the above statements one must have a realizing sense of the great length of the above arcs. The combined length of all the arcs used by Colonel Clarke in 1880 to deduce the figure of the earth was equivalent to 89 degrees of a great circle. The arc of the thirty-ninth parallel is equivalent in length to 37 degrees of a great circle; the Atlantic oblique arc is 22 degrees long, and the California oblique arc 8 degrees; and the combined length of these three arcs is 67 degrees, or more than two-thirds the total length used by Clarke.

The most interesting recent development in geodesy has been the investigations of variations of latitude. It may be asked, "Why is this investigation classed as geodetic rather than astronomic?" The answer is: It belongs in both classifications. Obviously it is an astronomical investigation, but it concerns the geodesist also; it concerns him directly, because the astronomical latitudes with which he must deal are now known to be a function of the time of observation. It is interesting to note also that many of the observations upon which our knowledge of the latitude variation depends were made with the zenith telescope, an instrument which the geodesist claims rather than the astronomer.

For ten years past there has been marked activity in investigating this question along two lines. One class of investigators worked by the inductive method, and slowly built up empirical mathematical expressions for the observed facts as to the variations, independently of any theory as to their causes. For this purpose they used many series of old observations, made at various fixed observatories, but not primarily for this purpose. In addition they have used many modern series of observations, made with zenith telescopes, for this special purpose. It has been shown that the motion of the pole in the past may be represented with considerable accuracy as a combination of two motions, each circular, one with a mean period of about 428 days and the other with a period of one year. A still closer approximation is obtained by assuming that the amplitude and epoch of each these motions is subject to a periodic variation. A somewhat closer agreement between the mathematical curves and the observations is secured when elliptical paths are substituted for the circular paths above referred to. The net result of the investigations by the inductive method has been certain mathematical expressions which closely represent the known facts of the past, but there is great uncertainty as to how far into the future these mathematical expressions may be extended, because their basis is wholly empirical.

The progress made along this empirical line of investigation has been due to Professor S. C. Chandler, of Harvard, more than to any other one man or, possibly, any group of men. His results have been published as the investigations proceeded in the *Astronomical Journal*, and form an exceedingly interesting series, not only on account of the remarkable success attained, but because of the ingenuity and skill shown in devising methods of investigation which are independent of any theoretical basis.

Another class of investigators has worked from the standpoint of pure theory. Their endeavor has been to furnish an adequate explanation for the observed facts. Up to the time when the latitude was shown, by direct observation, to be subject to periodic variations, one of the fundamental assumptions upon which astronomical computations were based was that the latitude of a given point on the earth's surface is invariable. Pure theory, indeed, indicated that the latitude of a point should be subject to a periodic variation of small amplitude with a period of about 305 days. Special investigations had failed to reveal a variation having that period, and astronomers had fallen back to the dogma of invariability. Theorists are now confronted with the necessity of accounting for a period of about 428 days instead of 305. It is known that any movements of the earth's crust and of the water and air in response to a displacement of the pole of figure from the pole of rotation have the effect of lengthening Euler's period. It has been shown that any difference in the equatorial radii also has a tendency to increase the theoretical period to correspond more nearly with the fact. The known atmospheric and oceanic currents have also been appealed to for an explanation. It has also been shown that it is not impossible that such impulsive forces as are concerned in earthquakes and volcanoes may produce some of the effects observed. The net result, however, of the investigations of theorists has been a series of partial explanations, no one of which stands all the tests which have been applied to it. Each fails, either by furnishing a law of motion which differs essentially from the observed facts or by being quantitatively inadequate.

This was the situation when the International Geodetic Association formulated and adopted a plan for determining the actual motion of the pole during a series of years with the highest attainable accuracy. The observations, in conformity with the plan devised by them, were actually begun in the latter part of 1899, and it is proposed to continue these observations uninterruptedly for at least five years. The plan of operations is that the actual motion of the pole shall be determined by simultaneous observations at four stations widely separated in longitude, at each of which an instrument of the highest precision is to be so used as to guard, as fully as possible, against all known sources of systematic error. The details of the plan have been worked out very carefully, and it is admirable in every respect.

The four stations selected are Gaithersburg, in Maryland, in longitude + 77; Ukiah, California, in longitude + 123; Mizusawa, in Japan, in longitude + 219, and Carloforte, on the small island of San Pietro, just west of Sardinia, in longitude + 351. One of these stations occurs in each of the four quadrants of longitude, reckoned from Greenwich. All are within three seconds of the parallel of 39° 8′ 10″. The conditions considered in selecting them, other than those indicated above, were that there should be nearly symmetrical conditions as to the character of the surface northward and southward of the station to avoid unsymmetrical refraction; that the hygienic, social, and climatic conditions should be such that the observer might remain healthy, comfortable, and contented; and finally in Japan and at the European station the region was carefully studied with reference to the probable frequency of earthquakes.

Two extra volunteer stations have now been added to these four, one at the Cincinnati observatory, which happens to be nearly on the parallel of the four selected stations, and one at Tschardjiu, in Turkestan.

The four principal observatories have been constructed with the utmost care, under specifications furnished by the International Geodetic Association, specifications designed to insure that observations shall not be vitiated by local differences of temperature. The observatory proper is surrounded by lattice-work to protect it from direct sunlight and the roof is double. During observations the roof is rolled back to leave an observing slit two meters wide. The walls are so low that the telescope projects above the roof during observations. This fact, together with the unusual width of the observing slit, puts the instrument virtually in the open air during observations.

The instruments used at the principal stations are specially designed zenith telescopes, by Wanschaff, of Berlin. The telescope has a focal length of about 51 inches, an aperture of $4\frac{1}{4}$ inches, and a magnifying power of 104. Aside from other minor peculiarities, two are especially noticeable. The barrel of the telescope proper is protected by an outer thin metallic tube, which is connected at but few points with the telescope proper, and serves merely to protect it against sudden changes of temperature. This false tube is pierced at various points to permit circulation of air in the space between it and the tube proper. The eyepiece is furnished with a reversing prism of peculiar construction, such that all observations may be made with the observing line apparently vertical and with the star apparently moving either upward or downward at the will of the observer. The observation upon one star consists of four pointings, two taken while the star is moving apparently upward in the field of view and two with the star moving apparently downward, the reversing prism being turned 180 degrees between these observations. If, then, the observer has a personal tendency to place the observing line too far to the right, this will have contrary effects in the two pairs of bisections, and the personal equation will be eliminated from the mean result. In so far as accidental errors are concerned, the few observations already made indicate a high degree of accuracy, the probable error of a single observation of a pair being about $\pm 0''.10$. Few series of observations yet made can show probable errors as small as $\pm 0''.16$.

The computed motion of the pole will be nearly independent of the errors in the assigned declinations of the stars, the effects of the errors of declinations being eliminated by the well-known group method. The stars to be observed are divided into twelve groups, and each group is observed for about two months (50 to 80 days, according to the time of year). During the first half of the period when group No. 2 is being observed group No. 1 is also being observed, and during the latter half of the period group No. 3 is being observed at the same time as group No. 2. Similarly, group No. 3 is observed first in connection with No. 2, and then in connection with group No. 4, and so on. The difference between the mean latitude from group No. 1 and the mean from group No. 2 during the period when both groups are being observed is obviously due to the difference of the mean error in declination of the stars of the two groups and to accidental errors of observation. This method of observation, after being extended throughout the whole cycle until group No. 12 overlaps group No. 1, furnishes a means of determining the declination correction to each group to reduce it to the mean of all the groups, and thus to eliminate the declination errors from the computed change in latitude.

As an additional precaution, the same list of stars is to be observed at all the stations.

The effect of an error in the assigned proper motions of the stars observed will be to make the latitude of any one station appear to increase or decrease with lapse of time, but will have no appreciable effect on the value finally derived for the motion of the pole; for, the same list being used at all stations, all the latitudes will appear to increase or decrease together. Both the Japan and the Maryland station, would appear, say, to have increasing latitudes, although they are nearly on opposite sides of the pole, and therefore this result could not be mistaken for an actual motion of the pole.

Aside from the precautions already indicated against abnormal refractions due to local conditions, the observations themselves have been planned so as to guard against errors arising from this cause. Each group contains six pairs which are used directly for computing the latitude variation, and of which very few have zenith distances exceeding 20 degrees. Each group also contains two pairs introduced for the special purpose of studying the actual refraction, and of which the zenith distance is about 60 degrees. The normal refraction at a zenith distance of 60 degrees is about four times that at 20 degrees; hence the two refraction pairs will furnish an effective method of determining any peculiarities of refraction which are sufficiently great to produce any appreciable effect upon the latitude pairs, provided such effect is one which increases with the zenith distance.

Any refraction effect which is analogous to a displacement of the apparent zenith, by a persistent barometric gradient, for example, will not be put in evidence by this test. To eliminate such an error, dependence is placed upon the fact that the final result is based upon observations at several stations varying greatly in longitude and in the surrounding climatic and local conditions.

It may seem at first sight that an annual variation in refraction would produce an apparent annual motion of the pole. This would be true if the motion of the pole were derived from observations at one station only. It will be seen, however, on further reflection that annual variations in refraction would tend to make all the latitudes along one parallel apparently increase and decrease together, and that therefore the computed motion of the pole would not be appreciably affected if these annual variations were of about the same magnitude at the different stations distributed around the pole.

To sum up, the discovery of the periodic motions of the pole was first made by a purely inductive method. The laws governing those motions have been slowly and painfully deduced by a continual application of the same method to old series of observations and to many new series made for the special purpose. Now a new campaign of observations, promising results more accurate than any hitherto obtained, has been commenced. The mean position of the pole for each fortnight of the next five years will probably be known within a radius of five feet. There is little prospect for improvement of the observational side of this question for many years. The new observations will furnish material for new triumphs of the inductive method in furnishing a still closer mathematical approximation to the unknown laws of motion of the pole. The interesting feature of this investigation is now that the theorists are at sea, so to speak. Will they at the end of the five years be able to furnish an adequate explanation for the new facts observed or, indeed, for those already known? It is on this theoretical side of the investigation that new energy is needed. Here is a golden opportunity for some one well versed in mechanics, astronomy, and geodesy.

JOHN FILLMORE HAYFORD.
U. S. COAST AND GEODETIC SURVEY.

*THE PLANKTON OF FRESH WATER LAKES.**

For some years I have been interested in the subject of the fauna of our fresh water lakes. This interest was first aroused in regard to the animals of the deeper parts of the lakes. The results of the explorations of the depths of the ocean were just becoming known. I had read in the older works that while the sea was densely populated along shore, and had what has become to be known as a 'pelagic' fauna and flora in the open sea, remote from land, the depths were a barren region utterly devoid of both animal and vegetable life. But later it had been shown that there was, even in the

* Address of the retiring President of the Wisconsin Academy of Sciences, Arts and Letters.

greatest depths, a fauna, not very abundant to be sure, but of great interest because of the strange peculiarities of some of the forms. With others I was profoundly interested in this work, and it lead me to conjecture whether there was not a field for investigation in the deeper waters of our lakes. At that time very little had been done in the way of any systematic study of the deeper waters of the lakes. I think the only extensive work on the subject was Forel's 'La faune profonde des lacs Suisses,' published in 1885. Professor Forel had begun his researches on the deep water fauna of Lake Leman in 1869, and had published various notices in the intervening years. In this country, so far as I know, the first publication in regard to the deep water fauna of lakes was in the first volume of the *Transactions of the Wisconsin Academy*, in a paper by Dr. Hoy, of Racine. He detailed how he had become interested in the food of the whitefish, and had examined their stomachs, finding certain animals that seemed new to science. A company was made up for a dredging expedition consisting of Dr. Hoy, Dr. Lapham, Professor Stimpson, Professor Andrews and Mr. Blatchford, and put in a day's work dredging on Lake Michigan in June, 1870. The result was the collection of a considerable number of animals. Especial importance was attached to the discovery of a *Triglopsis* and a *Mysis*, as they are marine genera, and their presence was supposed to indicate a former direct connection of Lake Michigan with the ocean.

In 1874 Professor Smith published a paper on the 'Invertebrate Fauna of Lake Superior,' reporting the existence of the same crustacea in Lake Superior which Dr. Hoy had found in Lake Michigan. The *Mysis* there, however, occurs in somewhat shallow water as well as in the greater depths. In both lakes it forms an important—perhaps the most important—constituent of the food of the white fish and lake trout. As I was located near a lake of considerable depth, a depth reputed to be anywhere between 400 feet and infinity, it occurred to me that I had an opportunity to carry out similar researches.

My own work on lakes, then, originated in a desire to know more about the abyssal animals. I soon found, however, that the problem was a serious and complicated one, involving a complete faunistic study of the lake. I was fortunate in finding on the bottom of Green Lake the same *Mysis*, which makes its home in Lake Michigan. These animals have not been definitely reported from any other lake in the United States, although *Mysis* is said to live in a lake in New York connected with the St. Lawrence. Here was a pretty problem in animal distribution. How did these animals make their way into Green Lake? Was it by way of the Great Lakes, or did they come at some time by a connection through the Mississippi Valley? I could not tell, and I cannot to-day, for it becomes a problem for the geologist rather than the zoologist. With this as a starting point I attacked the problem of lake faunæ, and the battle is still in progress with no indications of a conclusion of hostilities for many years to come.

During the decade in which I have been interested in limnology there has been a very considerable advance in our knowledge of the subject, and it will be my attempt to-night to summarize this knowledge, and make as clear a statement as I can in the brief time at my disposal of what is now known of the fauna and flora of fresh water lakes. Russell, in his work on North American Lakes, enumerates ten agencies which, acting separately or in combination, may produce lakes. So far as our Wisconsin lakes are concerned, the most important of these agencies is glacial action. Most of our lakes are simply the depressions caused by the unequal distribution of the glacial drift, or by interference with preëxisting drainage lines. Inasmuch as Wisconsin is not a mountainous state, it follows that these depressions are nowhere of great depth, and that we have no lakes which compare in depth with those located in mountainous regions. Most of our lakes are extremely shallow, few being more than forty or fifty feet in depth. Lake Geneva 142 feet, and Green Lake 237 feet, are our deepest bodies of water, while our largest lake, Lake Winnebago, probably does not exceed twenty-five feet. All lakes are temporary features of the topography. The outflowing water is all the time deepening the outlet and increasing the amount of drainage, while the inflowing water is bringing in material which gradually fills up the lake bed. This process goes on with comparative rapidity, and even in our new lake areas there are numerous examples of dead lakes where swamp vegetation entirely covers what was formerly an open sheet of water. The physical processes involved in the lives of lakes and the relation of the lake vegetation to these processes are very interesting, but this is not the time or place to discuss them, and they can only be referred to in passing.

The subject of the fauna of fresh water lakes has not been especially attractive to zoologists. This is but natural when we consider the great wealth of life in the ocean, and the comparative poverty of fresh water. Of the more important divisions of the animal kingdom the echinoderms and tunicates are entirely absent in fresh water, and the cœlenterates and molluscoidea are represented by few forms. Even the crustacea, which form the greater part of the plankton, and are present in such enormous numbers, have very few forms compared with the crustacea of the sea. It is to be expected that zoologists will be attracted by this wealth of material in the sea, and that most of them will in the future as in the past resort to the sea for their study. It was in the ocean that the ancestors of our fresh water animals dwelt, and it is amongst those animals that the student may expect to find the most information in regard to the development of life on the earth.

But the lakes have their fauna, a fauna of great numbers if not of great variety, and because of their isolation and somewhat peculiar conditions, present a very interesting study in the distribution of animals. Of course the best known members of this fauna are the fishes, whose numbers, habits, and food are fairly well known. Fish are so important for human food that a study of their habits comes to be a matter of commercial importance, and our Federal and State governments expend large sums of money for this investigation and for the practical work of rearing and distributing the spawn or young fish. In Wisconsin, too, as well as in some of the other northern States, it is a matter of great practical importance to maintain the numbers of game fish in our lakes simply for the purposes of sport. Until one has made the rounds of the summer resort lakes one has little idea of the multitudes of people who come to our State in the summer season, attracted largely by the opportunities for fishing. Hundreds of thousands of dollars are brought to us every summer in this way, and it is a good business policy which leads us to do all in our power, and even spend large sums of money, if necessary, to maintain our stocks of game fish.

It has long been known, of course, that fish are dependent for their food upon smaller animals, and it has also been known that a knowledge of these same small animals was necessary to any accurate and complete knowledge of fish, but this study was so difficult and involved so much drudgery that for a long time it was neglected.

Anything like an exact knowledge of the

crustacea may be said to date back only half a century to the writings of Fischer and Claus, although some papers upon this subject had been published previously.

In 1817 Say published a somewhat extended article on the crustacea of the United States, in which he speaks of one *Ostracod*, two *Daphnias* and one *Cyclops*, as inhabiting the waters of the southern states. In 1843, in the 'Natural History of New York,' was published an article by DeKay on the crustacea, which was beautifully illustrated, but added little to our knowledge of the fresh water crustacea. In fact, though *Cyclops* and *Daphnia* are mentioned, they are spoken of as 'extra-limital,' in spite of the fact that not a lake in New York would have failed to furnish him countless numbers of these genera, had he looked for them. To Professor Forbes, of the University of Illinois, is due the credit of making the first extensive collections of these animals in this country, and publishing accurate descriptions of them. His first paper was published in 1876, and was followed by a series of very valuable investigations, culminating within the last few years in the establishment of a floating laboratory on the Illinois River for the continued study of the fauna and flora of that river and the shallow lakes adjoining.

In Europe large numbers of investigators within the last few years have devoted themselves to the study of fresh water animals and plants. Preëminent among them have been Forel and his co-laborers on Lake Leman, and Zacharias and his fellow-workers in the station at Lake Plön in Holstein. This station at Plön was, I believe, the first permanent fresh water station in the world. Since its establishment in 1891, a considerable number of permanent stations have been established in various parts of the world. It is not my purpose here to give a history of these establishments, for that has already been exceedingly well done by Professor Ward. I may call attention in passing, however, to the fact that the work in this country has been done almost exclusively in our immediate vicinity, Illinois, Wisconsin and Michigan having published by far the most material on this subject. Similar work has been prosecuted in Minnesota, Ohio and Indiana, but very little has been done in the other states, if we except the exceedingly valuable work of Whipple.

In Wisconsin, work has been prosecuted on the Madison lakes and Green Lake for many years, and now, under the auspices of the Natural History Survey, a more extensive and systematic biological survey of the lakes is being made, probably a more extensive comparative study than has been attempted elsewhere. While this study is of especial scientific interest, as has been intimated before, it is of great practical interest in connection with the problems of fish culture. It may not be likely that, as suggested by a recent writer in *Forest and Stream*, the future angler will carry with him a thermometer and chart with a statement of the laws of vertical and horizontal distribution, but such study does give a fundamental knowledge which is of vast importance to the angler as well as to the fish culturist.

The terminology used in the study of the fauna and flora of fresh-water lakes, as in the sea, was formulated by Häckel. Under the term 'plankton' is included all living things, animal or vegetable, found in the water which do not move from place to place by their own volition. Fishes are not considered a part of the plankton. The life of the sea may be considered as 'littoral,' 'pelagic' and 'abyssal.' To these terms Häckel adds 'zonary,' to include those animals which are supposed to occur at zones of different depths in the open ocean. In the littoral and pelagic planktons we may have both animals and plants, but in the abyssal no plants are found. The study of the pelagic and abyssal faunas has been entirely within the last half century; in fact the very knowledge of their existence dates back hardly fifty years.

In the lakes we use a similar set of terms. The regions are 'littoral,' 'limnetic' and 'abyssal.' The characteristics of these regions are somewhat known, but still our knowledge is far from perfect.

A list of the plants and animals found in any one lake seems quite formidable because of its length, but the species that are present in any considerable numbers are very few. From a limnetic collection, for instance, we may find in abundance the following: Four or five copepods, five or six cladocera, three or four protozoa, and perhaps two rotifers. This would be a fair average fauna in one of our lakes. Of the plants, we would find two or three diatoms and as many algæ.

Not only are the animals and plants of neighboring lakes very much alike, but the same animals may be found distributed over wide territories, and even over different continents. This is true even of some of the higher animals of the plankton, like the crustacea. Of our fifteen species of *Cyclops* nine are found in Europe. In the case of one species it is not only found in Europe, but in Asia and in Africa, and literally does not vary a hair in these widely separated localities. On the other hand, the genus *Diaptomus* is very variable. We have not a single species which is common to the European lakes. Not only that, but there are many localized species in the United States. One species occurs, so far as known, only in a few lakes in the northern part of the lower peninsula of Michigan. A second is widely distributed in all the smaller lakes across the continent in the northern States. Another goes from the center of Wisconsin north into the Arctic regions. In the Rocky mountain regions are several peculiar species. Through the southern States two species are found which never come north. Mexico has at least one peculiar species. Of the other organisms, both animal and plant, most are world-wide in their distribution. From this fact of the general uniformity of fauna and flora over wide regions, it is clear that the study of a lake which simply produces a faunal and floral list is of very little value. There was a time when such lists were important, before this uniformity of distribution was determined, but that time is long since past, and those European authors who continue to fill the proceedings of learned societies with lists resulting from desultory explorations of one or more lakes are almost wasting printers' ink.

In the littoral region we find usually an abundant flora. Those plants which need an anchorage find it in the mud of the bottom, and the unattached plants are protected by those that are stationary. Protected by these plants and living upon them is an abundant fauna in which crustacea are the most prominent, although we find great numbers of rhizopods, infusoria, sponges, hydrozoa, worms, true insects and mites, mollusca and bryozoa. This abundance of the lower animals forms a rich supply of food upon which the higher animals can live. It is in this littoral region that the fish get the most of their food, and every fisherman knows that marshy borders are necessary to maintain the supply of fish. The animals of the littoral plankton are opaque, and generally are so colored that when they are at rest they are inconspicuous. Those that swim about and then drop to the bottom to rest are ordinarily so colored that they are not easily distinguished from the mud. Frequently in littoral regions the bottom is covered with a thick mat of *Chara*, which, in turn, forms hiding places for enormous numbers of the invertebrates.

The flora of the limnetic region can be, of course, only of floating plants. Among these are an enormous number of diatoms. *Chlorophyceæ* are present in larger or smaller numbers and sometimes large numbers of the *Cyanophyceæ*. Generally speaking the limnetic flora is not sufficiently abundant to attract attention, but on some lakes they are sometimes multiplied in such quantity as not only to attract attention but even to excite alarm. The surface of the lake has a thick coat of bright green, and as this is cast up on the shore by the waves it forms thick ridges which in their decay become very offensive. This phenomenon has been known in England as 'the breaking of the meres,' in Germany as the 'wasserblüthe,' and in this country as the 'working of the lakes.' The appearance is sometimes ascribed to the seeds of littoral plants. Only a few species of plants are concerned in this phenomenon, and the species differ somewhat in different lakes. Certain diatoms may be present, too, in sufficient numbers to produce an unpleasant 'fishy' smell in the water. This exaggerated growth of the limnetic flora is most pronounced in shallow or comparatively shallow lakes, and is frequently a source of great annoyance to cities which get their water supplies from such bodies.

The limnetic fauna, as I have said before in this address, has but few kinds of animals, by far the most numerous and characteristic being the crustacea. These are beautiful, transparent and nearly colorless creatures. It is not true, as is sometimes stated, that the limnetic fauna is entirely distinct from the littoral. The general character of the limnetic animals is certainly different, and distinctly different, from that of those found in the littoral region, but many individuals are common to both. It is true, however, that while there is hardly a radical distinction between the two faunæ, certain species are common in the limnetic regions and only rarely found in the littoral, while some that are everywhere in littoral collections are rarely found in those taken in the open water. There is, of course, no clear dividing line between the two regions, but one insensibly merges into the other, while, under the influence of the winds and waves, such limits as exist are continually changing.

In the species of crustacea there is a certain distinction between the limnetic fauna of the deeper lakes and that of the shallower. One species of *Diaptomus* is found everywhere in the Great Lakes, but in only three of the Wisconsin lakes—Lake Geneva, Green Lake, and Cedar Lake. The shallowest of these lakes—Cedar Lake—is about a hundred feet in depth. One of the species of *Cyclops* is very abundant in the Great Lakes, but is seldom found elsewhere except in comparatively deep lakes.

In a paper published in the Transactions of the Academy, I made the suggestion that lakes might be divided according to their faunæ into the deep water and the shallow water, suggesting as a possible limit between the two 40 meters. I have since found that Elhart Lake, 117 feet, and Cedar Lake, 95 feet, have many characteristics of the deep water fauna, and it is possible that the dividing line should be nearer 30 meters than 40.

The German authors make a distinction between 'plankton-poor' and 'plankton-rich' lakes, which very nearly corresponds to my deep-water and shallow-water lakes; for the total amount of plankton in the deep lakes is very much less than in the shallow lakes. This is easily explained. For the number of animals is, of course, dependent on the number of plants. Inasmuch as plants are dependent upon sunshine, they will grow in water only in those places that are reached by the sun's light. As the light of the sun penetrates in deep water only to a limited distance, the deeper parts of our lakes are entirely devoid of plant life. On the other hand in shallow lakes not only do we find the floating vegetation as in the deep lakes, but as the light reaches the bottom over a larger proportion of its surface, we have in addition a very large flora flourishing on the bottom. In some of the very shallow lakes nearly the whole bottom is covered with a rank vegetation. This is true, for instance, of Lake Vieux Desert. In Green Lake, on the other hand, inasmuch as the shores are somewhat precipitous, there is only a comparatively narrow margin on which can be supported a flora growing upon the bottom, while the larger part of the lake is so deep that only the floating vegetation can exist. It is easily seen, then, that a shallow lake will be 'plankton-rich' as compared with a deep lake. Fishermen recognize this fact, and expect the shallow lakes to be better for their sport.

It is evident, then, that the living limnetic vegetation must be at or near the surface, where it can have an abundance of light. Animal life, however, is not limited in this way. It was long ago shown that in the sea there was an abundant surface fauna and an abyssal fauna, but in regard to the condition of the intermediate region there has been some dispute. Agassiz has claimed that there is a region intermediate between the top and bottom, which is entirely devoid of life. This has been disputed by some authors, and late explorations seem to indicate that no region between the surface and bottom is entirely free from animals. A similar condition exists in the lakes. By far the most abundant fauna is at and near the surface, but animals are found in greater or less numbers at all depths. The larger part of the plankton is found within thirty or forty feet of the surface; but the same kinds of animals that form the fauna of the upper waters may be found at all depths, although in small numbers. *Limnocalanus* is an example of an animal which belongs to the intermediate regions. It, too, may be found in small numbers at any depth from the surface down, but it seldoms occurs in any considerable numbers outside the intermediate region.

Limnocalanus and *Daphnia pulicaria* are perhaps the only animals in fresh water which belong distinctively to the zonary plankton, although *Cyclops brevispinosus* is much more abundant between five and twenty meters than it is near the surface.

Collectors of plankton material have known that they could ordinarily make much more abundant collections at night than in the daytime. This has led to a belief that there is a vertical migration of the plankton, towards the surface at night, and away from it in the daytime. It was supposed that the whole body of the plankton moved up and down. This idea has been proved to be false. What movement there is is within quite narrow limits near the surface, and all members of the limnetic fauna do not, by any means, behave in the same way. They have most decided individual peculiarities, so that we cannot speak of the movements of the fauna as a whole, but each species must be considered by itself. Some of them do not move at all vertically, but have the same distribution from one end of the day to another. Others, like the larval forms of the copepods, are more numerous at the surface in the daytime than in the night. Some have a very pronounced migration. This is particularly true of *Leptodora* which is rarely found at the surface in the daytime, but appears at almost exactly forty-five minutes after sunset, remains at the surface during the night, and disappears again at just three-quarters of an hour before sunrise.

Most of the larger crustacea which form the great body of the plankton do migrate in this way, and it was natural, perhaps, to infer that the whole plankton moved up and down.

The limits of this vertical migration it is very difficult if not impossible to fix. Most of the movement is within one meter of the surface, the most marked changes being within one-half meter of the surface, and below three meters the amount of movement is very slight. Eight determining factors have been listed by Professor Birge as controlling the vertical distribution of crustacea: food, temperature, condition of the water in respect to dissolved oxygen and other substances, light, wind, gravity, age and specific peculiarities. Of these factors, by far the most important are food, temperature and light. Inasmuch as the food supply is controlled by temperature and light, we may speak of these two factors as, in the main, controlling the vertical distribution of the limnetic plankton. Of these two factors, temperature is the most important, although light has a marked effect on many species. In the winter season when the waters of all the lakes are very nearly uniform in their temperature from top to bottom, the vertical distribution of the limnetic fauna is much more uniform than in summer.

In the summer season the most marked changes in vertical distribution are correlated with the vertical changes in temperature. This is most distinctly seen in the deeper lakes. In these lakes it is a surface layer of greater or less depth which is warmed, the deeper layers feeling the effect of the summer's sun only very slightly. In Green Lake below 40 or 45 meters the temperature never rises above 6.11 degrees Centigrade, although the surface may run as high as 26.67 degrees C. In Lake Michigan the bottom temperature at depths of 360 feet is 4.2 degrees C., with a surface temperature of 18.3 C.

The change in the temperature from the top to the bottom is not a gradually decreasing one, however. A layer of water at the surface, which may be in midsummer some ten or twelve meters in depth, is very nearly uniform in temperature. From the lower surface of this layer there is a very rapid decrease in temperature for a short distance, and then a gradual decrease until a minimum is reached. This layer of sudden change in temperature is known as the 'thermocline,' and its position varies in depth with the season and the size of the lake. As the summer season progresses the thermocline grows lower. In the very shallow lakes the temperature during the summer season is nearly uniform through the whole depth. In Lake Winnebago, for example, there is seldom a difference between top and bottom temperatures greater than two degrees. In small lakes the thermocline is considerably higher than in large lakes. This is doubtless due to the influence of the winds, by which the small lake is less affected. This was very prettily illustrated in a comparison of the Waupaca lakes with Cedar Lake and Green Lake about August 1st of this last summer. In three of the Waupaca lakes—Rainbow, McCrossen and Beasley's, of which Rainbow is the largest and Beasley's the smallest, the thermocline was respectively at six meters, five meters and three meters. At the same time the thermocline of Cedar Lake was at eight meters, and the thermocline of Green Lake at eleven meters. The vertical distribution of the plankton has a very close relation to the thermocline, most of the animals being above it. *Limnocalanus*, *Daphnia longiremis* and *Daphnia pulicaria*, however, are found below the thermocline, and in some plankton-poor lakes the proportion of the other organisms below the thermocline is much larger.

It is evident that the circulation of the water is in the layer above the thermocline, and that below the thermocline there is insufficient oxygenation, and that this bottom layer must, too, hold a great deal of the dead and decaying material falling from the upper layers. It is a curious fact, first pointed out, I think, by Whipple, that the bottom waters of deep lakes are stagnant during both winter and summer, but have a period of overturning in spring and fall. This overturning may come with considerable suddenness when the waters have not been much agitated by the winds. We ordinarily think that water is so mobile that the heavier portions will immediately sink, and thus the water of greater density will always be at the bottom. It may happen, however, as in the fall, that the upper waters will cool off, and yet retain their position, so that the lighter water will actually be below. The lake is in a condition of unstable equilibrium. If, under these circumstances, there comes a heavy wind, the whole body of water will overturn.

It is at these two periods of overturning, as shown by Whipple, that the growth of diatoms is especially pronounced, and they are found present in enormous numbers in the limnetic plankton. This great growth of diatoms is explained in the following way: During the periods of stagnation diatoms or their spores, if diatom spores exist, accumulate at the bottom of the lake, inasmuch as their specific gravity is greater than that of water. They do not grow there, because sunlight is essential to their growth. At the bottom is accumulating during this period, too, a large amount of organic matter from the decay of organisms near the surface, and this, under the influence of bacteria, is transformed into material fitted for food for the diatoms: in this food material the nitrates are perhaps the most important. When the time of overturning comes, the diatoms or their spores rise to the surface, accompanied by these dissolved organic materials, and, under the influence of sunlight, an exceedingly rapid multiplication takes place. As the food materials are used up the numbers of diatoms decrease again. Other organisms, of course, show the effect of the overturning of the water, for many are directly or indirectly dependent upon the diatoms for food, and, besides, diatoms are not the only organisms which can make use of the food materials which are thus brought to the surface. *Diaptomus*, *Epischura*, *Limnocalanus* and two species of *Cyclops* show quite clearly these two periods of rapid production, although in some of these cases the results are complicated by the fact that the temperature of the surface water has a direct effect on the reproduction.

The matter of the annual distribution of the organisms of the plankton is a very interesting question, but is also a very complicated one. As has just been stated, certain of the diatoms have a distinct spring and fall maximum, and there are other organisms which, because of their dependence upon the diatoms, have similar periods of maximum growth. But there are other causes at work which control the growth of individual organisms, so that their optimum periods may come at very different times of the year.

Generally speaking it is probably true that the largest amount of plankton occurs in midsummer, although Yung says that the maximum development of plankton in Lake Leman is in May or June, and that the minimum is in March and September. Zacharias states that the maximum period for Lake Plön is about August 1st. Measurements of a large number of collections from various lakes in Wisconsin indicate that the maximum of plankton occurs in these lakes in the latter part of July. The exact period of maximum development may vary from year to year, and in different lakes, because of varying local conditions. The reason for this July maximum seems to be not because any considerable number of organisms have their highest development, but because of the fact that there is a greater variety of forms at this time than at any other time of the year. This is undoubtedly because of the peculiarly favoring conditions of temperature. It is this time of the year that seems to be especially favorable to the growth of the algæ. The 'water-bloom' may appear in June and remains sometimes until into September, but it is in July and August that it is present in the greatest quantity. This summer, on Lake Winnebago, it was most abundant during the latter half of August.

The minimum of plankton development is in the winter months, especially in January and February. At no time of the year, however, are either plant or animal forms wanting, and collections made through the ice will give a considerable variety of kinds, as well as numbers of individuals.

It will be noticed that the period of maximum plankton development corresponds to the time of highest temperature of the water, and that the period of minimum development corresponds to the time of lowest temperature, so that we can be certain that the one important controlling factor in the growth of plankton is the temperature.

Hensen and his co-laborers who worked out a very elaborate system of measuring the plankton of the sea claimed that the distribution of the plankton over wide stretches of the sea was nearly uniform. Granting this to be true, it evidently is possible by a series of collections and measurements to compare different parts of the ocean in regard to their productiveness in animal and plant life. This conclusion, that the horizontal plankton of the sea has a practically uniform distribution, has been accepted by the majority of scientists, although vigorously combated by Häckel.

Apstein has applied the same methods to the examination of lakes, and has concluded from his investigations that the plankton of lakes is uniformly distributed. It is easily seen that there is very good reason for assuming this to be the case from the actual conditions under which the plankton exists. The plankton consists of organisms that do not move voluntarily from place to place, and therefore do not change their positions. They are dependent upon heat and light for their development, so that their growth is mainly within from twenty to forty feet of the surface, so that a depth exceeding this would not mean any greater production of plankton—or in other words, the amount of plankton depends not upon depth, but upon surface.

This is a most important conclusion, if true, for it gives us an exact method by which we can compare one lake with another and determine their relative productiveness, or from a series of collections, determine the absolute annual productiveness of any body of water. Such determinations would have an important commercial value, for by them could be estimated the possibilities of fish production in a lake. The method was worked out in detail and very elaborately by Hensen. The collection was made by a conical net of bolting silk drawn vertically through the water, thus straining out the organisms of a column of water of the size of the opening of the net. Then the material was counted under the compound microscope by a very laborious process. In this way exact numerical values can be obtained not only for the plankton as a whole, but for the individual constituents. Most investigators use Hensen's methods with greater or less modifications, and they have been productive of very fruitful results. But, unfortunately—I say unfortunately, because we all like to claim exact results, and are prone to think that nature works according to certain inflexible laws—much of the laborious detail of the work is a waste of time.

The question of the uniformity of horizontal distribution has been discussed by various authors and with considerable vigor, but I think it must now be acknowledged, that while there is a certain amount of uniformity, so that, by a considerable number of collections, we can express within rather wide limits the amount of plankton at any time on a lake, uniformity in any exact sense does not exist. This lack of uniformity is largely due to a difference in the number of crustacea, although there are marked differences in the distribution of the other organisms. Surface growing plants, for instance, are moved about under the influence of the winds, and accumulate on the leeward side of a lake. If one part of a lake is deeper than another and the lake is not much disturbed by the winds, at the period of maximum growth the number of diatoms will be much greater over the deeper part. Crustacea may be in ill-defined aggregations which may be called swarms, and these swarms are not stationary in all cases, but move slowly, perhaps under the influence of extremely weak currents. Not only is there a considerable variation in collections made at different locations on a lake at the same time, but if a series of collections is made at the same place, the amount of the plankton in some collections may be twice as much as in others. An examination will show that these large variations are generally due to a difference in the numbers of some of the crustacea, showing conclusively that not only do the numbers of crustacea vary at different locations, but that these swarms are not stationary. It follows, then, that conclusions in regard to the plankton drawn from a few collections may be quite erroneous. If, however, a considerable number of collections is made, especially if they are made from widely-separated localities, the average of all these collections, allowing something of a margin for error, will give a fair idea of the amount of plankton in a lake. Of course, the larger the number of collections the less the amount of error, but anything like very exact results can not be expected. We are able, in this way, to compare the plankton of one lake with that of another, or to determine the relative amount of plankton at different times of the year on any single lake. But any estimate of the actual amount of plankton produced by a lake at any time or during the year must be acknowledged to be only an approximation. Care must be taken, too, in comparing one lake with another, that they be compared under similar conditions. The maximum of one lake may not be reached at the same period as that of another. The conditions of a deep lake are very different from those of a shallow lake, and a fair comparison can be made only by averaging collections continuing over a considerable period.

In the abyssal region, because of the lack of light, plant life is impossible, and the fauna is very meager.

It is true that the list of animals which have been found in the abyssal regions of lakes is a long one, including, as it does, protozoa, cœlenterata, worms, molluscs, bryozoa, crustacea, arachnida, insect larvæ, and some few fish, but an examination of any single lake shows that not only is the number of kinds small, but the numbers of individuals of any kind are very small. In Europe the abyssal fauna of Lake Leman has been worked up with great thoroughness. In this country very little detailed work has been done on this subject. It is not a fruitful field for research, and it is not strange that it has been neglected. In shallow lakes it is doubtful if there is any distinctive abyssal fauna. The most abundant animals in the mud of the bottom are worms, insect larvæ, gasteropod and lamellibranch molluscs, and amphipods. With these may be associated at times great numbers of other animals, as occasionally one finds in the mud of shallow lakes large numbers of fresh-water hydra. Most if not all these animals are identical with the littoral forms, and the difference between the littoral fauna and the deep-water fauna is that in the deep water those forms which are especially dependent upon the weeds for food and protection are lacking, while we find in abundance the mud dwellers.

In the abyssal regions of deep lakes, however, we find forms which are characteristic of those regions, although they may be mingled with others that are also found in the littoral region. In the abyssal region of Green Lake, which may be considered the typical deep-water lake of Wisconsin, are found, besides some undetermined worms, a little lamellibranch, *Pisidium*, ostracods, amphipods, insect larvæ and *Mysis*. There are some protozoa in the mud, but they have not been studied. The ostracods are so numerous that their shells form a conspicuous part of the bottom deposit.

In the smaller lakes of a depth ranging from 60 to 100 feet, like the Waupaca lakes and Elkhart, a different condition of things exists. The bottom is composed of a dark mud, and is almost completely devoid of life. This has been a puzzling fact, and has been to me personally a matter of considerable disappointment because of my interest in abyssal animals. The probable explanation seems to be that these depths are rendered unfit for life by reason of the more complete stagnation of the deep water in small lakes, and because of the larger amount of organic matter which is being decomposed there. Because of the small areas of such lakes, leaves are carried from the shore all over their surfaces, and, sinking to the bottom, increase largely the amount of decaying organic matter. Partly decomposed leaves are common in the bottom collections of small lakes but rare in lakes of the size of Green Lake or Lake Geneva. This may account largely for the black color of the bottom mud. Then, in a large lake, the winds indirectly produce slow bottom currents. A prevailing wind will pile up the water at the end of a lake; this water must return in some way, and there is good reason to think that at least a part of it returns by a slow bottom current. Professor Birge tells me that his temperature observations give evidence of such a movement of the water. It follows, probably, that in the large lake there is not perfect stagnation, and hence the conditions of the bottom are more favorable for animals than in a small lake. The larger the lake, then, other conditions being equal, the greater would be the abundance of abyssal life. While there have been no accurate means of comparing the abyssal fauna of the Great Lakes with that of the smaller lakes as to quantity, such collections as have been made would indicate that it is much greater in the Great Lakes, and decreases in proportion to the degree of stagnation. If my explanation proves to be the correct one, as I feel quite certain it will, it will follow that the small deep lake will be limited in its fauna in two ways: because of its steep shores it will have a small littoral fauna and flora, and because of its stagnant deep water it will have little or no abyssal fauna.

I have thus far spoken as though all lakes had the three faunæ: littoral, limnetic, and abyssal. Generally speaking this is true, even small bodies of water showing this distinction. But occasionally the distinction is almost lost. This is true in Lake Winnebago. In spite of its great size—the lake is some twenty-eight miles long by ten or twelve broad at its greatest width—it is only about twenty-five feet deep. In its fauna there is a curious mingling of littoral and limnetic forms, littoral forms being found in the open lake, and limnetic forms even among the weeds along shore. The explanation seems to be this: because of its slight depth the environment, even far from shore, is favorable to the growth of littoral forms. Then there is good reason for thinking that the winds have a profound effect on its waters, thus thoroughly mixing limnetic and littoral waters, and consequently causing a similar mingling of the organisms. Lake Winnebago has the characteristics, in many respects, of an enormously overgrown puddle. I do not say this, however, to show a lack of respect for this lake, for from a practical standpoint it is a most valuable possession to the state. It can support, and does support, an enormous number of fish. Few lakes can compare with it in productiveness.

All the inhabitants of fresh water are, of course, descendants of marine forms. In some cases the modifications have been very great but in others they are hardly to be distinguished from their salt-water relatives. This is true, as has already been stated, of some of the crustacea: in some of these it is difficult to make a specific distinction between the fresh-water and marine forms. Most of the environmental conditions in fresh water are so different, however, from those in the sea, that we should expect a fauna to develop itself which would differ widely from its ancestors.

It will be noticed that the most pronounced likeness to marine animals, perhaps, is found in the abyssal forms. So far as that is true, it may be explained, I think, by the uniformity of conditions existing in the depths of lakes. The temperature varies but a few degrees from one end of the year to another, and such currents as exist are slow and almost imperceptible. The abyssal fauna of a lake is subject to nearly the same conditions as that of the sea, except for the difference in the composition of the water. If, as has been supposed, the deep-water fauna of the Scandinavian lakes is descended directly from the deep-water fauna of the sea, coming from the sea into lakes having a communication with salt water, and surviving there after the lakes were cut off from the sea, and their waters had become fresh, we can see how the animals could gradually adapt themselves to their surroundings, inasmuch as the conditions of light, temperature and food supply would remain with very little change.

With the limnetic and littoral fauna, however, a very different condition exists. In our climate the temperature of the surface varies during the year from the freezing point to eighty degrees or more Fahrenheit. In shallow lakes, not only is there this variation of the surface, but the lake may be frozen to the bottom in winter, so that all forms which can not go into a resting stage of some kind are destroyed. The conditions of life are hard, and especial fitness is required in order to make survival possible. In the sea, on the other hand, the conditions even of the littoral and pelagic fauna and flora are much more uniform. It is not strange that the fresh-water animals and plants are of few kinds, and that generally they are very different from those of the sea. It is perhaps more strange that so many resemblances remain, and that the forms are so varied as they are.

To trace out the connection of the individual forms with their marine ancestors is, of course, the work of the specialists in zoology and botany. It may be noticed, however, that the present population of our lakes has come since the glacial period, in fact the lakes themselves only date from that period. So far, then, as the fauna and flora pass from one body of water directly to another, we may assume that the present animals and plants are descended from those that were pushed south by the ice, and that as the ice retreated they followed again towards the north.

Currents carry organisms from one part of a lake to another, and from one lake to another by connecting streams: in this way animals or plants introduced at the source of a river may be carried through its whole length.

From lake to lake, too, seeds, eggs and living animals are carried by water fowl attached to their feathers or in the mud upon their feet. This is not simply from one lake to its neighbor, but many of these birds take long flights before alighting, so that the organisms are scattered over a wide stretch of territory. It is in this way, probably, that we can account for the uniformity in the fauna and flora of the lakes and the wide distribution of some of the forms. Where conditions are similar, then, we may expect likeness in the fauna and flora. As we have seen already, temperature is the great controlling factor in distribution, so that in lakes of the same latitude or the same elevation, other conditions being equal, of which the principal is depth, we may expect close similarity in fauna and flora.

We may assume, then, that the littoral fauna and flora have had their origin from neighboring bodies of water, and that as the ice retreated, the lakes were populated, partly by direct migration between contiguous bodies of water, and partly by the aid of the winds, currents and water fowls The limnetic fauna and flora is descended either from littoral forms which have gradually adapted themselves to limnetic conditions, or from pelagic forms, which, in bays where the water was less salt or brackish, have become adapted to the conditions of fresh water and have been distributed by the same agencies as the littoral forms.

Part of the abyssal fauna is descended from marine forms directly, as in the 'fauna relicta' of the Scandinavian lakes, and in the case of some of the animals in our Great Lakes. Another part of the abyssal fauna is descended from littoral forms which have gradually moved into deep water, and have been modified to suit their new environment. All the abyssal fauna of the Swiss lakes is supposed to be of this character.

What I have said thus far applies almost exclusively to lakes of the temperate zones, for it is there that lakes exist in the greatest numbers, and it is upon such lakes that most of the work of investigation has been done. But there are lakes in warmer climates, and we may expect that a thorough study of them will give us much that is new and interesting. A striking example of the extraordinary interest that may be attached to such lakes is Lake Tanganyika in Africa. Some years ago it was reported that a jelly fish was abundant in its waters. This excited the curiosity of zoologists, for the medusa is a marine form, and very rarely is found in fresh water, the most noted case being of the one found in the basin in Regent's Park, which is supposed to have been brought with plants from some tropical country. The *medusa* of Tanganyika is one of four jelly fish known to live in fresh water, and the other examples are very rare. A special expedition was organized to make an exploration of Lake Tanganyika, and although this work was very imperfectly done, the results appear to be of great interest. Along with the ordinary lacustrine fresh-water fauna there is a fauna of marine origin, but this marine fauna is not closely related to modern forms. It does, apparently, closely resemble Jurassic forms. Indeed, it is said that were some of the forms referred to a paleontologist, he would not hesitate to say that they belonged to Jurassic times. Have we here, then, a 'fauna relicta' which dates back to Jurassic times? It is too early to answer this question with any certainty, both because of our imperfect knowledge of the fauna of Lake Tanganyika, and because of our great ignorance of the geology of that part of Africa. But the mere possibility that this may be true is startling, and should incite scientists to a thorough study of the fauna and flora of Lake Tanganyika and the other lakes of Central Africa. So far as explorations have gone this 'halolimnic' fauna as it has been named, is peculiar to Lake Tanganyika, but we may expect to find more or less of it in other lakes.

A few words in regard to the work on plankton which remains for the future investigator. It will, I think, be evident, that so far as exact and comprehensive knowledge is concerned, we have but entered a vast field. We know so little, that we can say that we are just beginning to place limits on our ignorance.

A systematic knowledge of the fauna and flora is a first and fundamental condition of comparative biological work. We need accessible manuals by which the animals and plants dealt with can be identified. Systematic work may not be the highest or the most satisfying to the investigator, but it is very necessary. The plankton student is met, at the very beginning of his work, with a difficulty that is almost a complete block to further progress; although the number of forms with which he has to deal in his plankton work may be very few, he has to have the knowledge of a specialist in each group in order to identify them. If a laboratory has a company of specialists, the material is quickly identified by passing from one to another. But if the investigator is by himself, he finds himself in a most discouraging situation. The literature of the various groups is scattered and fragmentary, and frequently is utterly useless to any one but a specialist. There is need of a manual, or rather a series of manuals, that shall so treat of the fresh water fauna and flora, that any well-trained biologist shall have no difficulty in identifying his material outside the group which he may have made his special study.

It seems to me that we have nearly reached the time when the publication of such a manual should be possible. Most of the preliminary work has been done. More, perhaps, remains to be done on the botanical side than on the side of zoology, for the exact study of the lower aquatic flora has been much neglected. I hope that the time is not far distant when we may have such a manual produced in this country, with the coöperation of our best specialists. Nothing would do more to further the study of plankton, for it would furnish the student with a tool of inestimable value.

In regard to the plankton itself, very little is really known of the abyssal fauna and its controlling conditions. I have spoken of the fouling of the water at the periods of stagnation, but our knowledge of the conditions of the water at those times is very imperfect. There should be a systematic examination, by chemical analysis of the water and its contained gases, and of the mud of the bottom, and an exact comparison should be made between the lakes with sterile bottom waters and those with a comparatively abundant fauna. In connection with this should be a study of the currents of the abyssal region. A more careful and thorough examination should be made of those lakes whose geological history indicates that they were formerly connected with the sea, and may contain a 'fauna relicta.' I may say that it is not likely that such explorations will yield any startling results. The time for that is probably past, and the lake student of the future must content himself with hard work, without the satisfaction of brilliant discoveries.

Our quantitative knowledge of plankton is only a beginning. We know something of the conditions on a few lakes, but only on a few, and we do not know what variations may be caused by the peculiarities of individual lakes. Even in the same lake the conditions may change from year to year, and in only a few instances have observations continued through a series of years. We are all prone to generalize on the facts in our hands, but it must be acknowledged that the facts upon which we can build theories of fresh water plankton are very meager. There is need of a series of examinations of typical lakes carried on for a term of years, before we can build with certainty.

There remains the great problem, or complex of problems, of the relation of the different elements of the plankton to each other and to the fish. We see, frequently, an apparent overproduction of one of the elements. In shallow lakes—at least in many of them—there is apparently a great overproduction of vegetation. How is this explained? How is the balance of life restored? What constitutes an ideal relation between the vegetable and animal growth? When we plant a new species of fish in a lake, we, of course, disturb the existing balance of organisms, may we not, in some cases, at least, work actual damage? To what extent is this balance between animals and plants maintained in a lake that is not interfered with by man?

These and similar questions, now without answers, offer a field of almost unlimited work, and work that is worthy the best efforts of our students. For while my address, in treating of the present condition of the study of lakes, has dealt largely with isolated facts, after all it is not the facts which the student pursues as his ultimate aim, but the general laws underlying the facts. He is an unfortunate man who sees the trees, but cannot perceive the forest, who can see the stones of which the cathedral is constructed, and show how they were lifted to their places, but cannot perceive the beauty of the structure as it stands in its exquisite proportions, its massive masonry and wealth of sculptured detail only serving to express the idea of beauty and harmony in the master mind of the architect.

RIPON COLLEGE.

SCIENTIFIC BOOKS.

The Cambridge Natural History. By DAVID SHARP, M.A. (Cantab.), M.B. (Edinb.), F.R.S. Vol. VI. *Insects* (Part II.). London and New York, Macmillan & Co. 1899. 8°. Pp. xii+626, and 293 cuts.

The completion of that portion of the Cambridge Natural History which is devoted to insects is an event of unusual importance to entomologists; for these two volumes constitute the most useful work of its kind that has appeared since the publication of Westwood's Classification of Insects.

The most striking feature of this work is the same as that which characterized Westwood's Classification and has made it an indispensable part of every entomological library; that is, it includes the results of a careful sifting of the greater part of all entomological literature. In a word, these two volumes of the Cambridge Natural History constitute an encyclopædia of entomology, written by one who has thoroughly studied the more important contributions to all departments of entomology, and who also contributes much that is new.

An admirable feature of the work is the fact that it is well-balanced; the morphology, the taxonomy, and the œcology of insects have each received sufficiently full treatment. The student of any phase of entomology is almost sure to find someting on his subject here and to find also references to the more important literature.

The author has placed entomologists under so great obligations to him that one does not feel like saying anything but praise of his work. I cannot help feeling, however, that it would have been better if in some respects he had been less conservative. This is especially true of his treatment of the larger divisions of the class of Insecta; his conclusions on this subject are hardly an advance on what might have been written a quarter of a century ago. In fact this is the weakest part of his work. Thus, in his discussion of Brauer's classification (Vol. V., pp. 175–176), he has apparently failed to grasp the most important point brought out by Brauer. He says (p. 175) that one of the chief characters on which Brauer bases his system is the existence or absence of wings ; and later (p. 176) he says "Thus it (Brauer's classification) begins by a division of Insecta into winged and wingless ; but the winged division is made to comprehend an enormous number of wingless Insects, whole subdivisions of Orders such as Mallophaga being placed in the winged series, although all are without wings." Now the fact is Brauer does not use the existence or absence of wings as a character distinguishing the two groups into which he divides the Insecta. Brauer believes that the wingless condition of the Thysanura and Collembola is due to their generalized condition ; that none of their ancestors had wings. On the other hand he believes that the wingless condition of all other wingless insects is a secondary condition, that they have descended from winged ancestors. In other words that existing insects represent two distinct lines of descent ; in one, the primitive wingless condition has been constantly retained ; in the other are found only descendants of a common-winged ancestor. This distinction is clearly indicated by the names he proposed for the two groups, Apterygogenea and Pterygogenea. The fact that many of the Pterygogenea have lost their wings does not militate in the least against this distinction. The only indication that our author has understood Brauer's position is a statement that "This first division is entirely theoretical." But if we give him credit for understanding Brauer we must blame him for stating the case in a very misleading manner.

As a rule, however, the work is written in a clear, simple style. The illustrations are abundant and are excellent ; and the pages present an attractive appearance. It is a work that no entomologist can afford to be without.

J. H. Comstock.

Traité de Zoologie Concrète. By Yves Delage and Edgard Hérouard. Tome 11, 1re Partie, Mésozoaires, Spongiares. Paris, Schleicher Frères. 244 pages 15 colored plates and 274 text figures. 1899.

In the most recent volume of their 'Concrète Zoology' Delage and Hérouard present, from the teacher's standpoint, one of the most difficult branches of Invertebrate Zoology, and only praise is due them for the excellent manner in which the subjects are treated.

The group including the two families Dicyemidæ and Orthonectidæ, to which Van Beneden gave the name Mesozoa as indicative of their supposed intermediate position between the Metazoa and the Protozoa is considerably enlarged by the addition of a number of forms which show less evidence of degeneration than do Van Beneden's original types. The classification, however, is only provisional, for in most cases the life history is not known and it is recognized that future investigations may show the forms in question to be only larval stages of other animals. With this in mind the authors make four classes of the Mesozoa as follows, the name of each class indicating the nature of the sub-ectodermal structures : (1) Mesocoelia.—Forms having a digestive cavity with no other cellular boundary than the ectoderm (Frenzel's *Salinella salve*). (2) Mesenchymia.—Forms having a parenchymatous tissue within the ectoderm and without a digestive cavity (*Trichoplax* and *Treptoplax* (Monticelli)). (3) Mesogonia.—Forms without digestive cavity and with one or several cells beneath the ectoderm which are destined for sexual reproduction (Dicyemidæ and Orthonectidæ). (4) Mesogastria.—Forms having a digestive tract like the archenteron of a gastrula, the walls being separated from the ectoderm by a coelomic cavity in which there is no intermediate tissue (*Pemmatodiscus*, a parasite on *Rhizostoma pulmo* (Monticelli)). In addition to these classes, Haeckel's Physemaria, the 'urn' forms in the cavities of the Sipunculidæ, and the curious form described by Caullery and Mesnil under the name *Siedleckia nematoides*, are included as appendices.

In the second part of the volume the authors put into their subject an intimate knowledge gained only by personal investigation and continued research upon the structure and the development of the Sponges. The result is a clear and concise presentation of the numerous complicated Sponge-structures. The canals, inhalent and exhalent, with their many confusing branches and chambers, are admirably portrayed and their mode of origin from the simple condition of an hypothetical rhagon-type is clearly shown. The spicules have received especial attention and the confusing nomenclature is presented in a table where ninety-eight different types of spicules are described and named in accordance with the views of Sollas, Lendenfeld, Stewart, and Schultze. With only eight exceptions a figure of the spicule accompanies each description and with this table, an average student for the first time, can classify Sponges while the admirable schematic figures of the organisms will help him to understand their structure.

The Sponges are divided as usual into two branches, CALCARIA and INCALCARIA. The former is subdivided into two orders, Homocœlida and Heterocoelida (both adapted from Poléjaef); the latter is further divided into two sub-classes, Triaxoniæ (F. E. Schultze) and Demospongiæ (Sollas). The first sub-class includes two orders, Hexactinellida (Zittel, Lendenfeld) and Hexaceratida (adapted from Lendenfeld); the second sub-class includes three orders, Tetractinellida (Marshall) Monaxonida (Ridley and Dendy) and Monoceratida (Lendenfeld). The further divisions are made in accordance with the nature and disposal of the spicules. An improvement in the editing of the volume, although of minor importance, is noted in the presence of the name of the family to which the various genera belong and this cannot fail to help the student.

As with the previous volumes disputed questions are clearly stated and the arguments on both sides are fairly presented, the authors in most cases taking a decided stand upon one side or the other. If a critic wished to hunt for defects in the work he might be successful in the section which treats of the physiology of nutrition; this portion of the volume is not complete enough.

In connection with the taxonomic position of the Sponges, the authors maintain with Hatschek, Perrier and Parker and Haswell that they represent a phylum entirely distinct from all other types. In their opinion one character is sufficient to justify separation from the Coelenterata and from all other groups. This feature is the fact first made out by Delage, that the germ layer which corresponds to the ectoderm of other Metazoa, passes during gastrulation to the interior, where it forms the choanocytes in the walls of the ciliated chambers, while the endoderm layer becomes superficial and forms the definitive external covering. They also state that ontogeny throws no light at all upon the relationships of the group.

GARY N. CALKINS.
DEPARTMENT OF ZOOLOGY,
COLUMBIA UNIVERSITY.

A Memoir on the Palæzoic Reticulate Sponges constituting the family Dictyospongidæ. By JAMES HALL in collaboration with JOHN M. CLARKE. (Memoir II, State Museum New York, 1898 [October, 1899], pp. 350, plates I–LXX, royal 4to. A portion of this work also appeared simultaneously with the same title, in the Fifteenth Annual Report of the State Geologist for the year 1895, Vol. II, pp. 743–984, plates 1–47.)

This volume is practically a continuation of the 'Paleontology of New York,' and had its inception in 1884. In 1890, but 42 species of *Dictyospongidæ* were known, and there are now described and figured all the paleozoic representatives of the living 'glass sponges,' of which there are 128 species. "This wonderful increase is not especially a matter for congratulation, save that it serves to show the amazing diversity of these silicious sponges in late Devonian and early Carboniferous faunas." All but 6 species are American. When the fact is noted that most collections contain but few specimens of these sponges, it is a surprise to learn that 70 species alone are found in the Upper Devonic of New York and Pennsylvania. It is mainly in New York that the great fossil 'sponge plantations' occur, and these have been and continue to be worked by Mr. Edwin B. Hall of Wellsville, to whom belongs the credit of having by far the largest collection of these extinct forms. From some of the New York localities several hundred specimens of a kind have been taken, but usually a single species is found in each or this may be even restricted to one colony.

Conrad (1842), was the first to record these fossils, regarding his *Hydnoceras* as a cephalopod. In the same year Vanuxem described another form, *Uphantænia*, as a plant, and this was the current interpretation for all the *Dictyospongidæ* until 1881, when Whitfield, from Lower Carbonic material, determined that they were the remains of sponges. Nearly all these fossils are found in sandstone, while the living *Euplectellas* are commonly anchored on muddy bottoms.

The present monograph begins with 'General Observations on the Sponges.' These are followed by sections on the affinities, structure of the skeleton, preservation, and occurrence, of the *Dictyospongidæ*. A detailed review of the bibliography, in which there are 42 entries, is next given, and then come a classification and the descriptions of genera and species. The family *Dictyospongidæ* is here divided into seven sub-families, all new. These are: *Dictyospongiinæ*, *Thysanodictyinæ*, *Calathospongiinæ*, *Physospongiinæ*, *Hyphantæniiæ*, *Hallodictyinæ*, and *Aglithodictyinæ*. Of new genera there are *Dictyospongia*, *Hydriodictya*, *Prismodictya*, *Gonglospongia*, *Botryodictya*, *Tylodictya*, *Helicodictya*, *Rhabdosispongia*, *Ceratodictya*, *Lebedictya*, *Thysanodictya*, *Arystidictya*, *Aclœodictya* *Griphodictya*, *Calathospongia*, *Clepsydrospongia*, *Roemerispongia*, *Hallodictya* and *Aglithodictya*. *Mastodictya* is another new genus, but is undefined. *Sphærodictya* is proposed to replace in part *Teganium* Rauff, which seems to include heterogeneous material. *Cyathophycus* is considered objectionable, because the name indicates a plant. On this ground Dawson changed it to *Cyathospongia*, a name used earlier by Hall. In this volume, the latter term is replaced by *Cyathodictya*. It is a question whether anything is gained by these changes (*Cyathophycus* to *Cyathodictya*, and *Uphantænia* to *Hyphantænia*).

Hydnoceras Conrad was proposed for 'an extravagant type of orthoceran cephaloped.' This, however, never came into use and is here revived 'not because it was founded on a misconception, but because it perpetuates one' (*sic*). On the other hand *Dictyophyton* was introduced by Hall in 1863, 'at the request of Mr. Conrad * * * to replace the term *Hydnoceras*.' The genotype is *D. newberryi*, which was also accepted for *Thamnodictya* in 1884. Under the rules of nomenclature such changes are not usually permissible, but since *Dictyophyton* 'tends to perpetuate the old and erroneous conception of the algous nature of these fossils' the name may be allowed.

The paleontology of New York serves as the highest expression of the work on American invertebrates, not only from a scientific standpoint, but also in artistic appearance. This volume on the sponges continues the previous standard, in spite of the fact that the preservation of the extinct glass sponges does not permit of much detailed elaboration. From an artistic standpoint, the present monograph is equalled by no other, not even by the elaborate 'Systeme Silurien du Centre de la Boheme' of Barrande. Professor Hall long ago recognized the accurate and artistic draughtsmanship of Mr. George B. Simpson and the ability of Mr. Philip Ast in lithographic work. Few can appreciate the skill and patience of the latter in overcoming technical difficulties. For 50 years New York has nobly supported her workers in pure science, and paleontologists look to that Commonwealth and to Dr. Clarke for a continuance of the splendid series of volumes on the paleontology of the State.

Charles Schuchert.

Man and his Ancestor. Charles Morris. New York and London. The Macmillan Co. Pp. vi + 238. $1.25.

SCIENTIFIC JOURNALS AND ARTICLES.

The January number (Vol. I., No. 1) of the *Transactions* of the American Mathematical Society contains the following articles: 'Conics and cubics connected with a plane cubic by certain covariant relations,' by H. S. White; 'Formentheoretische Entwickelung der in Herrn White's Abhandlung über Curven dritter Ordnung enthaltenen Sätze,' by P. Gordan; 'Sur la définition générale des fonctions analytiques, d'après Cauchy,' by E. Goursat; 'On a class of particular solutions of the problem of four bodies,' by F. R. Moulton; 'Definition of the Abelian, the two hypoabelian, and related linear groups as quotient-groups of the groups of isomorphisms of certain elementary groups,' by L. E. Dickson; 'Note on the unilateral surface of Moebius,' by H. Maschke; 'On regular singular points of linear differential equations of the second order whose coefficients are not necessarily analytic,' by M. Bôcher; 'The elliptic sigma-functions considered as a special case of the hyper-elliptic sigma-functions,' by O. Bolza; 'On the groups which are the direct products of two subgroups,' by G. A Miller; 'On certain crinkly curves,' by E. H. Moore; 'A new definition of the general Abelian linear group,' by L. E. Dickson.

THE February number of the *Bulletin* of the American Mathematical Society contains the following articles: Report of the annual meeting of the Society, by the Secretary; a report of the December meeting of the Chicago Section, by Professor T. F. Holgate; 'On cyclical quartic surfaces in spaces of n dimensions,' by Dr. Virgil Snyder; 'On the singular transformations of groups generated by infinitesimal transformations,' by Professor Henry Taber; 'Proof of the existence of the Galois field of order p^r for every integer r and prime number p,' by Professor L. E. Dickson; a review of Méray's Infinitesimal analysis, by Professor E. Lovett; 'Notes'; and 'New Publications.'

THE contents of the March number of the *American Journal of Science* are as follows:

'Hot Water and Soft Glass in their Thermodynamic Relations,' by C. Barus.

'Conrad's Types of Syrian Fossils,' by C. E. Beecher.

'Electrical Thermostat,' by W. Duane and C. A. Lory.

'Toxic Action of a Series of Acids and of their Sodium Salts on Lupinous Albus,' by R. H. True.

'Explorations of the *Albatross* in the Pacific,' by A. Agassiz.

'Ægirite Granite from Miask, Ural Mountains,' by L. V. Pirsson.

'Illinois Gulch Meteorite,' by H. L. Preston.

'Silurian-Devonian boundary in North America,' by H. S. Williams.

SOCIETIES AND ACADEMIES.

THE ANNUAL MEETING OF THE NEW YORK ACADEMY OF SCIENCES, FEBRUARY 26, 1900.

PROFESSOR HENRY F. OSBORN, President of the Academy, opened the meeting with a brief address in which he spoke particularly of the needs of the Academy in reference to a permanent home, and a larger publication fund; of the work of the sections of the Academy, particularly of that of the Section of Anthropology and Psychology, in association with the recently organized Ethnological Society; and of the Section of Astronomy and Physics, which has lately added Chemistry to its field of operations. Professor Osborn paid brief tribute to certain of our distinguished Honorary members who have died during the year, particularly to Professor Bunsen, Dr. Geinitz, Sir William Dawson, and Sir William Flower.

The Recording Secretary reported a total of 333 resident members, and analyzed the 82 papers given before the Academy during the last year, as to their subjects, showing that the largest attention has been given to anthropology, astronomy, geology, paleontology, petrography, physics, and zoology. The Recording Secretary also reported that the annual reception and exhibition which was held in April, in the American Museum of Natural History, was, like its predecessors, extremely successful. For the first time since the reception has been held in the American Museum it was possible to have an unoccupied room, whereby there was no confusion between the Academy and Museum exhibits. The same plan will be followed during the coming year. The Academy feels that it owes a great deal to the President and Trustees of the American Museum of Natural History, for their kindness and courtesy in allowing the Annual Reception to be held in the Museum, under such favorable auspices, and at such a moderate expense to the Academy.

The Council feels that the success and increased interest evident in the meetings since the removal of the meeting place to its present building (12 West 31st Street) is a very pleasing feature in the Academy's work. Almost without exception the meetings of the various sections have been individually and as a whole largely increased in attendance during the last year and a-half.

"The work of the Recording Secretary's office has been systematized and in many ways improved during the last year, so that the necessary and frequent details are managed more efficiently and with less expenditure of energy and time."

The Treasurer reported cash on hand \$2239.11, with total assets of \$15,059.11.

The Librarian reported that the library consisted in round numbers of about 9000 volumes, of which hardly 5 per cent. are in separate title. During the year the library has been well housed in Schermerhorn Hall, Columbia University, the card catalogue and shelf list have been rearranged and the library in every way has been made more workable and serviceable.

The Editor reported that Vol. XII. of the *Annals*, now in press, of which one part has already appeared, contains 14 papers, and about 600 pages. He also reported the appearance of Part I., Vol. II. of the *Memoirs*, devoted to 'The So-Called Devonian Lamprey, *Palæospondylus gunni*,' by Dr. Bashford Dean. The edition of the *Annals* has been increased from 1000 to 1250, and the exchange list has been extensively revised.

The following Honorary and Corresponding Members were then elected, and nine resident members were, 'because of their scientific attainments and services,' made Fellows:

Honorary Members.—Julius Hann, Ph.D., University of Graz; Edward Charles Pickering, LL.D., Harvard University; Jules-Henri Poincaré, F.R.S., Faculty of Sciences, Paris; Henry Augustus Rowland, LL.D., Johns Hopkins University; Edward Burnett Tylor, D.C.L., LL.D., F.R.S., University of Oxford.

Corresponding Members.—Albert De Lapparent, École Libre de Hautes Études, Paris; William Henry Holmes, United States National Museum, Washington, D. C.; Kakichi Mitsukuri, Ph.D., Imperial University of Tokyo, Japan; George Howard Parker, Ph.D., Harvard University, Charles Richard Van Hise, Ph.D., University of Wisconsin; Sho Watasé, Ph.D., Imperial University of Tokyo, Japan.

Fellows.—Dr. W. S. Day, Secretary Section of Astronomy, Physics and Chemistry; James Douglas, President American Institute of Mining Engineers; Jonathan Dwight, Jr., Ornithologist; Dr. Marshall A. Howe, Curator Columbia University Herbarium; Professor Charles H. Judd, Professor of Psychology, New York University; Dr. E. G. Love, Entomologist; Alfred W. Trotter, Mining Expert and Civil Engineer; Dr. Henry S. Washington, Petrographer; Dr. Theodore G. White, Paleontologist.

The list of officers given below was then elected by ballot:

President: Robert S. Woodward.

First Vice-President: Charles A. Doremus.

Second Vice-President: Franz Boas.

Corresponding Secretary: William Stratford.

Recording Secretary: Richard E. Dodge.

Treasurer: Charles F. Cox.

Librarian: Livingston Farrand.

Councillors: Daniel W. Hering, Frederic S. Lee, Harold Jacoby, M. I. Pupin, Edw. L. Thorndike, L. M. Underwood.

Curators: Harrison G. Dyar, Alexis A. Julien, George F. Kunz, Louis H. Laudy, E. G. Love.

Finance Committee: Henry Dudley, John H. Hinton, Cornelius Van Brunt.

After a brief address by the President-Elect, the retiring President delivered his presidential address, entitled 'The Geological and Faunal Relations of Europe during the Tertiary period, and the Theory of the Successive Invasions of the Ethiopian Fauna,' which will be printed in this JOURNAL.

RICHARD E. DODGE,
Recording Secretary.

AMERICAN MATHEMATICAL SOCIETY.

THE first number has recently appeared of the *Transactions of the American Mathematical Society*, published quarterly by the Society with the coöperation of Harvard University, Yale University, Princeton University, Columbia University, Haverford College, Northwestern University, Cornell University, The University of California, Bryn Mawr College, The University of Chicago; edited by Eliakim Hastings

Moore, Ernest William Brown, Thomas Scott Fiske; New York, The Macmillan Company. The *Transactions*, which is devoted to the publication of important researches presented at the meetings of the Society, is quarto in size, and the annual volume will contain not less than five hundred pages. The contents of the first number are noted elsewhere.

The Annual Register of the Society has recently been issued, and contains a directory list of publications, list of officers and members, Consitution and By-Laws, and annual reports. Copies may be obtained from the Secretary.

A regular meeting of the Society was held at Columbia University on Saturday, February 24, 1900. As usual, the programme occupied a morning and an afternoon session. President R. S. Woodward occupied the chair. A part of the afternoon was devoted to a joint meeting with American Physical Society, at which a paper on Latitude Variation was presented by Professor J. K. Rees.

A revision of the By-Laws, affecting mainly their arrangement, was adopted. Notice was also given of a proposed amendment of the Constitution enlarging the Council by making the ex-presidents permanent members and increasing the number of elected members by three. The following persons were elected to membership in the Society: Professor Anne L. Bosworth, Rhode Island College, Kingston, R. I.; Mr. H. L. Coar, University of Illinois, Urbana, Ill.; Dr. F. R. Moulton, University of Chicago, Chicago, Ill.; Mr. F. G. Radelfinger, Hydrographic Office, Washington, D. C. Two applications for membership were received.

The following papers were presented at this meeting:

(1) DR. ALEXANDER MACFARLANE: 'On the nabla of quaternions.'
(2) DR. M. B. PORTER: 'On the number of roots of $F(\alpha, \beta, \gamma, x)$ between zero and 1.'
(3) MR. H. W. KUHN: 'List of the imprimitive groups of degree fifteen.'
(4) DR. G. A. MILLER: 'On the groups of isomorphisms.'
(5) DR. J. I. HUCHINSON: 'The Hessian of the cubic surface, II.'
(6) PROFESSOR MAXIME BÔCHER: 'Some theorems concerning linear differential equations of the second order.'
(7) PROFESSOR J. K. REES: 'Results of seven years' observations for variation of latitude and the constant of aberration, made at the Columbia University Observatory.'
(8) DR. G. W. HILL: 'On the extension of Delaunay's method in the lunar theory to the general problem of planetary motion.'
(9) PROFESSOR E. B. VAN VLECK: 'On linear criteria for determining the circle of convergence of a power series.'
(10) PROFESSOR F. MORLEY: 'The metrical geometry of the plane n-line.'
(11) PROFESSOR L. E. DICKSON: 'Two triply infinite systems of non-isomorphic simple groups of equal order.'
(12) PROFESSOR L. E. DICKSON: 'Isomorphism between certain systems of simple linear groups.'
(13) DR. L. W. REID: 'A table of class numbers for cubic number bodies with the method of their calculation.'

After the meeting many of the members dined and passed a pleasant evening together. The next meeting of the Society will be held on Saturday, April 28th. The Chicago Section meets at Northwestern University, Evanston, Ill., on Saturday, April 14th. The summer meeting of the Society will be held in New York, in June, in affiliation with the meeting of the American Association for the Advancement of Science.

F. N. COLE,
Secretary.

COLUMBIA UNIVERSITY.

THE TEXAS ACADEMY OF SCIENCE.

THE regular monthly meeting of the Texas Academy of Science was held in the Chemical lecture room of the University of Texas on Friday evening, January 12th, President Simonds in the chair.

The first paper on the program, entitled, 'The Red Sandstone of the Diablo Mountain, Texas,' was by Mr. E. T. Dumble, of Houston, formerly State Geologist. The sandstone here discussed is found north of Allamore station on the Texas and Pacific Railway, and is the rock enclosing the copper vein, a part of which has been known for some years as the Hazel mine. Professor Streeruwitz in one of his reports on the region states that this formation is possibly Devonian, basing his statement, as Mr. Dumble understands it, entirely on the petrographic character of the rock, as it contains no fossils, and on its relation to the Carboniferous deposits in the hills north of the mine. Mr. Dumble has studied this sandstone, if it really be such, with considerable care, and finds it to occupy a position much lower in the geological scale than had been previously thought—that it is, in fact, below the Texan Group of Comstock—that is, at the very base of the sedimentary series. He does not believe that it is a part of an immense mass or boss of igneous material.

Mr. A. C. McLaughlin, for several years past connected with the Geological Survey of Maryland, gave an account of the work as conducted by that organization in the western part of the State.

Professor T. U. Taylor, of the Department of Engineering, read and commented upon a communication received from Professor W. H. Echols, of the University of Virginia, on the 'Measure of Earthwork,' in which the prismatic formulæ were employed.

Dr. S. E. Mezes followed with a paper on 'Monogamous Marriage,' in which he gave an account of this institution and of the rules and customs by which it has been maintained. That this institution is adapted to the highest civilization was shown in the fact that by it, and it alone, could be made a home, and that the home-training of children produced the highest and best results socially. The paper was both thoughtful and candid and received the hearty approval of all who heard it.

F. W. S.

UNIVERSITY OF TEXAS.

DISCUSSION AND CORRESPONDENCE.

MARGINAL TABS FOR LOGARITHM TABLES.

To THE EDITOR OF SCIENCE: Will you permit me, through the columns of SCIENCE, to bring to the attention of users of my 'Computation Rules and Logarithms,' a set of 'Marginal Tabs' for use in that book. The tabs are arranged for the five-place tables of logarithms of numbers and of the trigonometrical functions. They not only materially lessen the time required to find any logarithm or antilog in the use of the tables to five places, but they render the table even more speedy than the ordinary four-place table for obtaining the logarithms or antilogs to four places, while also much lessening fatigue and liability to mistake, no interpolation being required. The printed tabs, with directions for their application and use, form a leaflet which will be mailed by the author on receipt of twenty-five cents. Copies of the *errata* of the first (very thick paper) impression of the Tables, but which have been corrected in later impressions, will be mailed to holders of that edition on receipt of a stamped and addressed envelope.

S. W. HOLMAN.

18 ELM STREET, BROOKLINE, MASS.,
February 24, 1900.

NOTES ON PHYSICS.

IN the London *Electrician* is a report of some recent experiments of Professor S. Lussana on the variation of resistance under high pressures, up to 1000 atmospheres. He found the resistance to decrease with increase of pressure, and obtained the following coefficients per atmosphere.

Lead	194×10^{-7}		
Iron	38	Argentana	9.7×10^{-7}
Silver	32	Nickelina	7.4
Copper	31	Constantea	7.9
Platinum	24	Manganin	5.6
Nickel	19	Brass	4.3

The curves of decrease of resistance were slightly concave toward the axis of pressure, showing a tendency toward a minimum.

The resistance did not return to its normal immediately on removal of the pressure. In the case of platinum which had been under a pressure of 500 atmospheres for one hour, the resistance, on removal of the pressure, increased rapidly for ten minutes, and then quite slowly, taking about one hour to return to approximately its normal. Held under the same pressure for 24 hours, the curve showing its return with time to normal resistance is very interesting, rising in about 50 minutes to normal, going above, returning again to normal in about 7½ hours, falling below, and again becoming approximately normal in about 14 hours, thus showing a series of waves of decreasing magnitude and increasing length.

In the same journal of January 26th is an abstract of a Royal Society paper by C. E. S. Phillips, on 'Diselectrification produced by Magnetism.' Foil was cemented on the inner and outer surfaces of a glass tube, and powerful magnet poles were inserted through air-tight flanges. When the tube was exhausted below .2″ of mercury, and the inner coating was connected to the positive side of an electrical machine, an electroscope attached to the inner coating showed a rapid discharge on opening or closing the circuit of the magnet. With higher pressures or when the inner coating was negative there was no effect. When the electroscope was attached to the iron of the magnet poles, it indicated that the charge was transferred to these.

F. C. C.

ZOOLOGICAL NOTES.

BIRD MIGRATION.

IN a recent issue of the *Proceedings of the California Academy of Sciences*, Leverett M. Loomis gives a fourth part of his 'California Water Birds,' including his deductions from a careful study of their migrations. He concludes that the Shearwaters off Monterey find their position and shape their course by landmarks, and that birds possess no mysterious superhuman faculty for determining direction, or else these same Shearwaters would not have been bewildered in the fog. He also considers that the young are guided from the place of their birth to their winter abode through the experience of the older birds, and that the mere presence of young alone in a locality does not prove that they are migrating independently of the adults, but that older birds have either continued their flight or are migrating farther off. Mr. Loomis sums up by saying that bird migration is a habit evolved by education and inheritance which owe their origin and perpetuation to winter, with its failure of food.

THE STEREORNITHES AGAIN.

IN the December number of *Communicaciones del Museo Nacional de Buenos Aires*, Senor Mercerat discusses the zoological position of the gigantic birds from the Santa Cruz beds of Patagonia, and considers them as an independent 'gens' of the suborder Ciconiiformes of Fürbringer. While this is all right, Senor Mercerat unfortunately adds that the Stereornithes are a degenerate group of birds, but that they have not progressed so far on their downward course as the so-called Ratitae, and that they present numerous characters similar to those of the Carinatae, combined with others peculiar to the Ratitae. What these ratite characters are, aside from the feeble development of the wings, no one has yet satisfactorily explained, and Mr. C. W. Andrews, in his recent memoir on *Phororhacos*, shows very clearly that the Stereornithes have no kinship with the Ostriches. Size and flightlessness are not morphological characters and have no bearing whatever on the systematic position of the bird. It was a favorite remark of the late Professor Cope that an animal a mile long and an inch wide might belong to the same genus as one a mile wide and an inch long, and this might be paraphrased by saying that a bird with wings twenty feet across might be the nearest relative of a bird with no wings at all.

F. A. L.

THE ASSAY COMMISSION.

THE Assay Commission, which is appointed annually by the President to test the weight and fineness of the coinage of the mints in operation during the preceding year, met at the Philadelphia mint on February 14th. The men whom President McKinley designated to serve for the year 1900 were: Senator John P. Jones, of Nevada; Representative E. J. Hill, of Connecticut; Dr. H. S. Pritchett, Superintendent of the Coast and Geodetic Survey; Professor S. A. Lattimore, of the University of Rochester; Professor H. H. Nicholson, of the University of Nebraska; Dr. J. A. Mathews, of Columbia University; Dr. Cabell Whitehead, Assayer of the Bureau of the Mint; Dr. Marcus Benjamin, of the Smithsonian Institution; Hon. John H. Perry, of Connecticut; Calvin Cobb of Boise, Idaho; Thomas B. Miller of Helena, Montana; Edward Harden, of New York City; E. H. Rich, of Fort Dodge, Iowa, and Francis Beidler, of Chicago. The Commission also includes three ex-officio members, viz., the judge of the District Court of the

Eastern District of Pennsylvania, Judge McPherson; the Comptroller of the Currency, Hon. Charles G. Dawes, and the Assayer of the New York Assay Office, Dr. Herbert G. Torrey.

The work of the Commission consists in counting, assaying and weighing samples representing the coinage of the mints at Philadelphia, New Orleans and San Francisco. For this trial one one-thousandth of all gold coins and one two-thousandth of all silver coins made during the year are sent to the Philadelphia mint under seal and kept for the meeting of the Commission. The coinage during the past year was larger than ever before and hence the labor of the Commission was increased. The trial pieces numbered over forty-one thousand. The work of the Commission was divided among three committees; the chairman of which, as announced by Mr. George C. Roberts, Director of the Mint were: Counting, Hon. E. J. Hill; Assaying, Dr. H. S. Pritchett; Weighing, Dr. J. A. Mathews. The investigations of these committees serve as a check upon the accuracy of the work at the several mints, as well as upon the Bureau of the Mint in Washington.

SCIENTIFIC NOTES AND NEWS.

Since making appropriations in March, 1899, of $500 to Professor Charles L. Doolittle, and of $300 to Mr. Henry M. Parkhurst, from the Benjamin Apthorp Gould Fund, a considerable additional amount of income has accrued, for the distribution of which the Directors are prepared immediately to arrange. Applications for appropriations may be made by letter to Mr. Lewis Boss, Albany, Dr. Seth C. Chandler, Cambridge, or to Professor Asaph Hall, Cambridge.

An item in the Urgency Deficiency Bill, which has now passed both Houses of Congress, makes an appropriation of $7500, for continuing the biological and economic investigations on the lobster and clam. The investigations deal with the practical aspects of the subject, and it is purposed to carry on the work in all States having clam and lobster fisheries, from Maine to Delaware inclusive.

A committee, consisting of Mr. James E. Scripps, Mr. George W. Bates, of Detroit, and Professor Francis W. Kelsey, of the University of Michigan, was appointed at the annual meeting of the Detroit branch of the Archæological Institute of America, and was instructed to name a general committee to prepare a memorial to be submitted to the next State Legislature on the subject of an archæological survey of Michigan. The present knowledge of Michigan archæology is meagre, and is given in 'The Data of Michigan Archæology,' by Harlan I. Smith, published in the *American Antiquarian* for May, 1896.

The University of Edinburgh will confer the degree of LL.D., on Eleanor A. Ormerod, the entomologist. The University of Edinburgh has not hitherto conferred an honorary degree on a woman.

Wabash College, situated at Crawfordsville, Indiana, has conferred an honorary degree of Ph.D. on Professor Asa H. Morton, professor of romance languages, at Williams College. If Professor Morton has not been consulted in regard to this doubtful honor, he may see fit to decline it.

Dr. Charles W. Dabney, president of the University of Tennessee, has received notice from the French Government of his appointment as a member of the Committee on International Awards at the Paris Exposition.

Professor R. W. Wood, of the University of Wisconsin, who is now in England, will return to Madison at the end of March after visiting Berlin and Paris.

Mr. William C. Whitney has presented two fine bisons to the New York Zoological Park. One of them is from the herd of the late Austin Corbin at Blue Mountain Park, N. H. The other is from Mr. Whitney's herd at Lennox, Mass.

Professor E. J. McWeeny, professor of pathology and bacteriology at the Catholic University of Dublin, has been appointed to the newly created post of bacteriologist to the Irish Local Government Board.

The trustees of the Philadelphia Academy of Surgery announce that the Samuel D. Gross prize was not awarded on January 1st, as no suitable essay was presented. It will be awarded on October 1, 1901. The prize, the value of which is $1,000, is awarded to an American citizen for an essay not exceeding 150 octavo pages, containing original investigations on surgical pathology or surgical practice.

THE Senate Sub-Committee, responsible for the bill interfering with vivisection in the District of Columbia, gave a hearing on February 21st. Among those who opposed the bill were Professor H. P. Bowditch, Surgeon General Sternberg, Professor W. W. Keen, Professor W. H. Welch, Professor William Osler, Professor Howard A. Kelly, Professor H. H. Hare, Dr. Mary P. Jacobi, and Bishop Lawrence.

WE regret to record the death of M. Émile Blanchard, member of the section of anatomy and zoology of the Paris Academy of Sciences.

WE must also announce the death at the age of 76 years of Dr. Hermann Schaeffer, honorary professor of mathematics at Jena.

IT is perhaps not generally known that the late Professor D. E. Hughes, the physicist and inventor, whose death we were recently compelled to record spent about twenty years in the United States. He was educated at Bardstown, Ky., where he afterwards taught 'natural philosophy.'

THE first part of Römer und Schaudinn's *Fauna Arctica* has appeared. It is a beautiful quarto, and contains papers by Schulze, Thiele, von Linstow and Ludwig, on the Hexactinellidæ Proneomenia, the Nematodes and Holothurians, respectively.

DURING the present month lectures on metallurgy are being given at the American Museum of Natural History under the auspices of Columbia University. The lectures, which are on Saturday evenings, are as follows:

March 3. 'The Constitution of Steel as revealed by the Microscope,' by Professor Henry M. Howe, of Columbia University.

March 10. 'The Constitution of Metallic Alloys in the Light of Modern Research,' by Mr. Albert Sauveur, Lecturer on Metallurgy, Harvard University.

March 17. 'Toledo Blades: Rationale of the Procedure in Manufacturing them and other Steel Objects explained by the Microscope,' by Henry Souther, Consulting Engineer, of Hartford, Conn.

March 24. 'Lead Smelting in the United States,' by Professor H. O. Hofman, of the Massachusetts Institute of Technology, Boston, Mass.

March 31. 'Aluminium,' by Professor J. W. Richards, of the Lehigh University, South Bethlehem, Pa.

THE thirteenth Lecture Course on science and travel at the Field Columbian Museum will be given during March and April on Saturday afternoons at 3 o'clock. The subjects and dates of lectures are as follows:

March 3. 'The Age of Steel,' by Mr. H. W. Nichols, Assistant Curator, Department of Geology, Field Columbian Museum.

March 10. 'Conditions of Life in Inland Lakes,' by Dr. E. A. Birge, Professor of Zoology, University of Wisconsin.

March 17. 'Gigantic Fossil Reptiles from the Jurassic of Wyoming,' by Mr. E. S. Riggs, Assistant Curator of Paleontology, Field Columbian Museum.

March 24. 'Primitive American Art with Illustrations Drawn chiefly from Studies in Aboriginal Games,' by Mr. Stewart Culin, Director of the Museum of Science and Art, University of Pennsylvania.

March 31. 'Archæological Discoveries on the North Pacific Coast of America, by Mr. Harlan I. Smith, American Museum of Natural History, New York.

April 7. 'Soyaluna, a Hopi Winter Solstice Ceremony,' Stanley McCormick Expedition, by Rev. H. R. Voth, Missionary to the Hopi Indians.

April 14. 'The 'Struggle for Existence' as a Factor in Animal Development,' by Dr. D. J. Rettger, Indiana State Normal School, Terre Haute, Indiana.

April 21. 'The Yellowstone National Park,' by Professor J. P. Iddings, University of Chicago.

April 28. 'Indian Tribes of the Great Plains,' by Mr. James Mooney, Bureau of Ethnology, Washington, D. C.

A TELEGRAM has been received at the Harvard College Observatory from Professor J. E. Keeler at Lick Observatory stating that the following elements and ephemeris of Comet '*a*' were computed by Professor Perrine.

Time of passing perihelion	$= T =$ 1900 April 29.08
Perihelion minus node	$= \omega =$ 24° 37′
Longitude of node	$= \Omega =$ 40° 25′
Inclination	$= i =$ 146° 25′
Perihelion distance	$= q =$ 1.3289

Ephemeris.

Computed from observations on February 3d and 8th.

UNIVERSITY AND EDUCATIONAL NEWS.

Mr. A. W. Grabau has been appointed instructor in geology in the Rensselaer Polytechnic Institute, Troy, N. Y.

Oberlin College receives $75,000 by the will of the late Mrs. Caroline E. Haskell of Michigan City, Indiana, and $40,000 by the will of the late William Osborne of Pittsburg.

By provision of the will of the late Dr. John Stanford Sayre, U. S. N., retired, Princeton University will receive $40,000, part of which is for the endowment of fellowships in applied chemistry and in applied electricity.

Under the will of the late Mr. Joseph Kaye, the Medical Department of the University College of Sheffield has received £1000 for the purpose of founding a scholarship for second-year students.

We learn from *Nature* that by the will of the Mr. W. Hiddingh, who died on December 10, 1899, the University of the Cape of Good Hope is bequeathed the sum of 5000*l.* for the foundation of a scholarship to enable young persons to pursue and complete a course of professional study, the scholarship to be tenable for four years. To the University is also bequeathed the sum of 25,000*l.* for the purpose of building a university hall and suitable university offices, and a large piece of ground for the site of the building. The South African College will receive the sum of 10,000*l.* for the erection of a students' building.

The University of Nebraska celebrated its thirty-first anniversary on February 15th, known as 'Charter Day,' by an oration by Dr. Allen R. Benton, Chancellor from 1871 to 1876, and since then of the faculty of Butler University, Irvington, Ind. After the oration, degrees were conferred upon six students who had completed the work for the degree of B.A., and upon one who had completed the work for the degree of B.Sc. The Regents, at their Charter Day meeting, discussed again the all-year-plan, *i. e.*, the plan of having four quarters of instruction, as in the University of Chicago. The subject was again referred to the Regents' Committee on Courses of Study. Dr. T. L. Bolton, of Clark University, was elected Instructor in Philosophy, to fill the place made vacant by the recent death of Dr. Leon M. Solomons. Although the chancellorship was discussed, no election was made. It is the expectation of the Regents to make an election at their April meeting. The new Experiment Station Hall was accepted from the contractors, and it will be occupied at once. A contract was let for the completion of Grant Memorial Hall, by the building of a large transept which will double the capacity of the hall. The sugar-beet industry, in Nebraska, having passed the experimental stage, the Regents ordered the discontinuance of the sugar-beet experiments on the Experiment Station.

Another bill has been introduced into the Senate, establishing a University of the United States. The bill provides that the government of the university shall be vested in a board of regents to be composed of the President of the United States, who shall be president of the board; the Chief Justice of the United States, who shall be vice-president of the board; the commissioner of education, the president of the university, the secretary of the Smithsonian Institution, the president of the National Academy of Sciences, the president of the American Association for the Advancement of Science, the president of the National Educational Association, the president of the American Association of Agricultural Colleges and Experimental Stations, the president of the American Historical Society, the president of the Washington Academy of Sciences, the presidents of the ten institutions of learning exclusive of State universities having the largest number of graduate students doing systematic original work; the presidents of the ten State universities having the largest number of graduate students engaged in like manner; the presidents of the ten other institutions, in as many States, not otherwise represented, having the largest number of students in the senior class of the academic departments, and six other citizens who, with their successors, shall be appointed by the President of the United States, by and with the advice and consent of the Senate. It is provided that 'University Square,' recently occupied by the old naval observatory, in this city, be the site for the national university.

MEDAL IN HONOR OF DANIEL GARRISON BRINTON.

Struck by the Numismatic and Antiquarian Society of Pennsylvania.

SCIENCE

Friday, March 16, 1900.

CONTENTS:

MSS. intended for publication and books, etc., intended for review should be sent to the responsible editor, Professor, J. McKeen Cattell, Garrison-on-Hudson, N. Y.

DANIEL GARRISON BRINTON.

The Memorial meeting in honor of the late Dr. Daniel Garrison Brinton was held at the hall of the Historical Society of Pennsylvania on the evening of the 16th of January, under the auspices of the American Philosophical Society, by twenty-six learned societies. The societies represented at the meeting were:

Academy of Natural Sciences of Philadelphia.
American Antiquarian Society.
American Association for the Advancement of Science.
American Folk Lore Society.
American Museum of Natural History.
American Oriental Society.
American Philosophical Society.
Anthropological Society of Washington, D. C.
Bureau of American Ethnology.
Chester County Historical Society.
Field Columbian Museum.
Geographical Society of Philadelphia.
Historical Society of Pennsylvania.
Jefferson Medical College.
Loyal Legion.
Modern Language Association of America.
New Jersey Historical Society.
Numismatic and Antiquarian Society of Philadelphia.
Oriental Club of Philadelphia.
Peabody Academy of Science.
Peabody Museum of American Archæology and Ethnology.
Smithsonian Institution.
United States National Museum.
University of Pennsylvania.
Wyoming Historical and Geological Society.

The program of the meeting was as follows:

1. Introductory by the presiding officer, representing the American Philosophical Society, by Provost Charles C. Harrison.

2. Presentation of an oil portrait of Dr. Brinton, the gift of friends to the American Philosophical Society, by Hon. Samuel W. Pennypacker.

3. Acceptance on behalf of the American Philosophical Society, by Dr. J. W. Holland.

4. Memorial Address, by Professor Albert H. Smyth.

5. Presentation of a collected set of Dr. Brinton's works, the gifts of his family to the American Philosophical Society, by Rev. Jesse Y. Burk.

6. Acceptance in behalf of the American Philosophical Society, by Mr. Joseph G. Rosengarten.

7. Address by Major J. W. Powell, of Washington, D. C.

8. Presentation of a medal bearing Dr. Brinton's portrait in relief, the gift of the Numismatic and Antiquarian Society to the American Philosophical Society, by Mr. Stewart Culin.

9. Acceptance on behalf of the American Philosophical Society, by Dr. J. Cheston Morris.

10. Address on the Ethnological Work of Dr. Brinton, by Dr. W J McGee, of Washington, D. C.

The meeting was called to order by provost Charles C. Harrison of the University of Pennsylvania and letters of regret were read from Major J. W. Powell, Miss Alice C. Fletcher, Mr. Frank Hamilton Cushing, The Marquis de Nadaillac and others.

Provost Harrison in his opening address, after eulogizing Dr. Brinton's attainments and services to science, referred to his gift to the University of Pennsylvania, before his death, of his priceless library of books on American languages and suggested that a Professorship of American Archæology be founded at the University to bear the title of the 'Brinton' chair.

The portrait of Dr. Brinton, presented by a number of his friends to the American Philosophical Society, was painted by Thomas Eakins, an artist who had known Dr. Brinton intimately.

The presentation of the portrait was made by the Hon. Samuel W. Pennypacker, Vice-President of the Historical Society of Pennsylvania, and accepted by Dr. J. W. Holland, Dean of the Jefferson Medical College, where Dr. Brinton had received his medical education. Professor Albert H. Smyth then delivered the Memorial address which was followed by the presentation to the American Philosophical Society by the Rev. Jesse Y. Burk of a complete set of Dr. Brinton's published works, a gift to the Society from Mrs. Brinton.

Major Powell was unable to be present on account of illness and his place on the program was assigned to Professor F. W. Putnam who urged the foundation of a memorial chair of Anthropology in the University of Pennsylvania in honor of Dr. Brinton, "covering the whole subject in the broad way which Dr. Brinton himself covered it in his lectures to students."

Mr. Culin then presented in behalf of the Numismatic and Antiquarian Society of Pennsylvania a bronze medal of Dr. Brinton cast by Mr. John Flanagan an American artist in Paris, and struck by the Society in commemoration of the 40th anniversary of its existence and the 15th of Dr. Brinton's presidency.

After the acceptance of the medal by Dr. Cheston Morris, on behalf of the American Philosophical Society, Dr. W J McGee delivered an address on the ethnological work of Dr. Brinton.

The meeting was largely attended, the societies participating sending delegates who were present.

A full report of the proceedings will be published in the Memorial Volume of the Philosophical Society which is about to go to press, and an edition of the part relating to the Brinton meeting will be printed and bound separately for distribution to libraries and institutions. This book will contain a bibliography.

THE FACILITIES AFFORDED BY THE OFFICE OF STANDARD WEIGHTS AND MEASURES FOR THE VERIFICATION OF ELECTRICAL STANDARDS AND ELECTRICAL MEASURING APPARATUS.

THE need of adequate facilities for the official verification of standards and measuring apparatus of all kinds, has long been recognized by American physicists. The Office of Weights and Measures, with its small force, modest equipment and insufficient appropriations, has endeavored to meet any demands imposed upon it within the limits thus set.

The object of this article is to describe what has thus far been accomplished along electrical lines, and in this connection a brief history of the units of reference may not be considered out of place.

The origin of standards of quantity and value dates back as far as the earliest historical records. The transition from the crude measures of antiquity to the systems meeting present requirements has, however, been exceedingly slow, although the growth of commercial intercourse gradually led to the introduction of more precise standards.

The requirements of accuracy were, nevertheless, quite modest until physics began to emerge from its qualitative stage to assume the dignity of an exact science.

The number and complexity of physical quantities at first led to the adoption of more or less arbitrary standards of reference, often based on the physical properties of some definite substance, *e. g.*, the calorie, and as long as the relations between physical quantities remained obscure, such relative standards sufficed. With the development of the science came the recognition of the desirability of a consistent system of units, which was strongly brought to the front, when it became necessary to measure magnetic quantities.

The happy solution of this problem suggested by Gauss and extended to the measurement of electrical and electro-magnetic quantities by Weber, constituted a great advance in the science of Metrology, the units being defined in terms of the mechanical actions to which they give rise. Since all mechanical units can be expressed in terms of three independent fundamental units, such as those of length, mass and time, the magnetic and electrical units of Gauss and Weber are thus expressible in terms of the same fundamental units and are therefore entirely independent of the physical properties of arbitrarily chosen substances. Hence they are called absolute units, their magnitudes depending solely on the choice of the fundamental units.

The units of length and mass selected were usually multiples or sub-multiples of the corresponding metric units, the metric system being the only one meeting the highest scientific and practical requirements and being already in extensive use. While at first uniformity in the selection of the magnitudes of the fundamental units was lacking, the centimeter, gram and second have now been universally adopted, the derived units being known as C. G. S. units.

Practical measurements of electrical resistance were, however, first referred to a variety of arbitrary standards, *e. g.*, the resistance of a given length of copper or iron wire of given diameter, and so long as electrical measurements were confined to the laboratory, the length referred to was usually a few feet, but with the practical applications of electricity to telegraphy and submarine signaling, this length became inconveniently small and was therefore replaced by fathoms, miles, etc. Fortunately none of these units ever gained general acceptance. In 1848 Jacobi pointed out that it would be far preferable to adopt, as a universal standard, the resistance of a certain piece of wire, copies *having the same resistance* being easily constructed.

Jacobi carried this suggestion into practice by sending a piece of copper wire, since known as 'Jacobi's Étalon' to various physicists for that purpose.

In 1860 Werner von Siemens proposed as a standard of resistance, the resistance, at 0°C., of a column of mercury, 1 sq. mm. in cross section and 100 cm. in length.

In 1861 a committee, composed of the most eminent English physicists was appointed by the British Association to consider the question of Standards of Electrical Resistance. Correspondence was opened with the leading foreign physicists and various special investigations of the problems, with which the committee was confronted, were undertaken by its members.

The first question settled was that the unit of resistance should be defined as a multiple by an integral power of 10 of the unit of Weber's absolute system, and that the unit chosen should be of a convenient magnitude. Accordingly, a unit equivalent to 10^9 C. G. S. units was adopted.

This definition fixed the unit, but the evaluation of a resistance in absolute measure requires the construction of especially designed apparatus, having usually a limited range of usefulness ; the determination of instrumental constants, most frequently involving tedious mathematical approximations, and in addition, the observations have to be made with the greatest precision. On the other hand, relative measurements require simpler apparatus and less skill in manipulation, besides being, in most cases, far more accurate than absolute measurements. The construction of material standards adjusted to the specified resistance, determined once for all by a series of absolute measurements, was therefore decided upon.

Investigations were made to determine whether the absolute unit of resistance could be accurately defined in terms of the resistance of a definite portion of a definite substance. Pure metals in the solid and liquid state and alloys were studied with this end in view. On account of the excessive influence on the resistance produced by small quantities of impurities in metals and by small variations in the composition of alloys and on account of the additional difficulty of procuring chemically pure materials, the choice was greatly limited. Moreover solids had to be rejected on account of the marked effect of physical changes produced by drawing, bending, annealing, etc.

Mercury, already recommended by Siemens, was therefore the only material to be further considered. Even this material was rejected, owing to large differences found to exist between coils, supposedly adjusted to agree with different German mercury standards, and the mercury standards constructed by members of the committee.

Having abandoned the above propositions, the alternative remained of constructing material standards adjusted with reference to the absolute unit.

A number of new alloys, in addition to many already in use, were made and investigated. An alloy of 2 parts by weight of silver to 1 part by weight of platinum was finally selected as best meeting all requirements. A special form of resistance standard was also adopted.

In 1863 and 1864 the values of certain coils were determined in absolute units by one of the methods proposed by Weber and from these measurements the B. A. unit was derived. A number of copies were issued gratis by the Association and in addition arrangements were made to furnish others at a moderate price. The B. A. unit soon gained universal acceptance in the English speaking countries, while the Siemens unit still retained its supremacy on the continent.

In 1878 it was shown by Professor Rowland that the B. A. unit differed from its assumed value by more than one per cent. and soon after, this difference was substantiated by a number of other investigators.

In 1881 a call was issued, in connection with the first Paris electrical exhibition, for an international electrical congress for the purpose of adopting definitions of the electrical units to serve as a basis for legislative enactments. Numerous mercury standards had in the meantime been constructed and had been found to agree most satisfactorily with one another; moreover, the results of a considerable proportion of the absolute determinations made had been referred, directly or indirectly, to the Siemens unit. In view of this, the Paris Congress passed a resolution recommending that all absolute determinations in the future be expressed as the resistance of a column of mercury of stated length, 1 sq. mm. in cross section at the temperature of melting ice, and that the C. G. S. electro-magnetic system of units be adopted. The desirability of making new determinations of the ohm was urged.

Three years later the Congress reassembled at Paris and adopted 106 cm. as the length of the specified column of mercury, individual results still differing by as much as ± .5 per cent. The unit of resistance thus defined was called the legal ohm, but while it was never legalized anywhere, it nevertheless came into extensive use, especially in England and in America.

Absolute methods were gradually improved, sources of error were pointed out, and eliminated as far as possible and accordingly the results of absolute determinations, made by the most radically different methods, became more concordant.

The International Electrical Congress (which met in Chicago in 1893), through its Chamber of Delegates, officially representing all the leading governments, therefore adopted, as the unit of resistance, the mean of all the best determinations, the resistance at 0° C. of a column of mercury 106.3 cm. in length and of uniform cross section having a mass of 14.4521 gm. (equivalent to a cross section of 1 sq. mm., the density of mercury being assumed to be 13.5956). The unit of resistance and the other electrical units defined by the International Congress were legalized in the United States by Act of Congress in 1894, and have also been legalized in the other countries represented.

It was generally supposed that the various governments would sooner or later take up the construction of mercury standards as called for in the definition since each had already been provided by the International Bureau of Weights and Measures with the fundamental standards of mass and length.

The Imperial Physico-Technical Reichsanstalt in Berlin has already begun this task with its characteristic thoroughness. Two one ohm mercurial standards were constructed and later, a third together with a ½ and a two ohm tube. Widely different cross sections were purposely selected to avoid possible sources of error. The calibration and intercomparison of these standards leaves almost nothing to be desired, measurements made by two different methods, both yielding the same results within the limits of experimental error.

Twelve mercury copies were also constructed; these, together with 7 working standards of manganin wire, periodically referred to the primary standards, complete the list.

In England, on the other hand, the B. A. coils have still been retained as primary standards. The legal ohm was defined in that country by the relation, 1 Siemens unit = .9540 B. A. units, and later the International Ohm was defined by the relation, 1 Siemens unit = .95351 B. A. units. According to a comparison made several years ago, 1 Siemens unit, as derived from the Reichsanstalt Standards, is equal to .95341

B. A. units, indicating a change in the coils themselves, or in their assumed relation to the Siemens unit or in both.

Matters have been still further complicated in England by the legalization of the resistance of a coil marked 'Board of Trade Standard verified 1894,' and adjusted with reference to the Cambridge Standards, as the unit of resistance.

A still more radical suggestion was made in that country several years ago, by Professor A. Viriamu Jones and Professor W. E. Ayrton, that each government adopt a Lorenz apparatus from which to derive by absolute measurements the unit of resistance. The practical substitution of an absolute method with its disadvantages as pointed out above, for a purely relative one seems to be taking a step or indeed several steps backward, but may be taken as indicating the lack of confidence in the permanency of the B. A. coils.

After the legalization of the International Electrical Units it became the imperative duty of our government to provide facilities for the official verification of electrical standards and electrical measuring apparatus, especially in view of the continually increasing importance of the applications of electrical energy to the industral arts. This function obviously devolved upon the Office of Standard Weights and Measures. already equipped for the verification of standards of length, mass, capacity, etc.

Owing, however, to the limited force and to the still more limited appropriations available for the purchase of apparatus, practically nothing could be done until July 1, 1897, when the appointment of a verifier was authorized, but unfortunately progress has frequently been interrupted for long periods by the pressure of routine work.

It was determined from the outset that it should be the aim of the Office to provide facilities for measurements to any degree of accuracy likely to be set even by the most exacting demands of modern science. The first steps taken by the Office consisted in working out a general plan and providing the most needed apparatus and facilities.

STANDARDS OF RESISTANCE.

To avoid the delay which would naturally arise from the construction of primary mercury standards, it was decided to refer all measurements of electrical resistance to the mean value of a number of wire coils, known in terms of the best existing mercury standards. The general excellence of coils of the Reichsanstalt type, the extremely small temperature coefficients and thermo-electromotive power with respect to copper of manganin and the permanency of coils of that material as shown by long continued observations at the Reichsanstalt, decided in favor of standards of the above description.

Four unit coils were purchased and were standardized at the Reichsanstalt where they were kept under observation for about one month, during which period they decreased in value by about .0015%. This, according to the maker, is the normal behavior of the material which undergoes, after the artificial aging, a small decrease in resistance followed by a slow increase. In addition to these coils the Office possesses two other coils of the same type purchased several years ago. Periodic intercomparisons between the old coils and the new ones will be made so that any relative changes will be made manifest, the two hardly having the same rate of change. Two new manganin coils have been ordered and are also to be referred to the German Standards. On their receipt, they will furnish us positive evidence in regard to any changes which may have taken place in the preliminary standards adopted. The approximate corrections at any time can then be determined by simple interpolation.

To fix this standard, the construction of a number of mercury copies will also be taken up. The construction of primary mercury standards, which is of fundamental importance, not only from a scientific standpoint but also on account of the legal questions which will surely arise, will be undertaken as soon as time permits.

The Office has acquired in addition to the unit coils, standards of the following denominations:

1	2	Ohm
1	5	"
4	10	"
4	100	"
3	1,000	"
2	10,000	"
2	100,000	"
3	0.1	"
3	0.01	"
3	0.001	"
3	0.0001	"

The temperature coefficients of these coils were first carefully determined, then the coils of the same denomination were intercompared and the observations reduced to differences at 20° C.

The next step consisted in determining the resistance of the multiples and submultiples in terms of the unit. Thus, two unit coils placed in series by means of a connecting link of known resistance were compared with the two ohm coil. The five and ten ohm coils were similarly evaluated in terms of the unit. From the known ratio of a 10 ohm coil to one of the units, the step can be made to the 100 ohm coils by means of a second ten ohm coil also known in terms of the unit. Similarly the values of the coils of still higher value were determined and those of the sub-multiples of the unit, by a slightly modified method.

THE METHOD OF COMPARISON ADOPTED.

The practice in this country and in England has been overwhelmingly in favor of the Carey Foster method, but the construction of the Reichsanstalt standards, with their terminals 16 cm. apart, makes the use of the Carey Foster Bridge almost out of the question. The design of a suitable bridge capable of comparing coils of this type with those having a different distance between the terminals, introduces still further complications. Moreover, in the Carey Foster method, additional resistances are introduced in the mercury cups of the commutator which are only eliminated in a perfect mechanical construction. Besides the resistances connecting the coils to the commutator, unless equal, are *not* eliminated. While the Carey Foster method is at first glance superior in being a zero method, the Wheatstone Kelvin Bridge, more simple and far less expensive in construction, excels the former especially where the intercomparison of low resistance standards is concerned, provided the coils to be compared are first made nearly equal by means of a shunt of known value applied to the greater. The value of the shunt need not even be known to a high degree of accuracy in case of fairly well adjusted coils.

The coils are connected to one another by copper forgings 1.5 cm. thick and 2 cm. wide, having therefore a resistance of about 0.6 micro-ohm per cm. of length, their terminals resting in mercury cups. To permit the comparison of coils differing widely from the standards, provisions have been made to enable one of the coils compared, to be placed in parallel with an accurately known coil by means of a second pair of mercury cups.

The sources of error characteristic of the direct deflection method are due to the following causes:

(1) Variation of E. M. F. of test battery.

(2) Variation of galvanometer sensibility, due either to the variation of proportionality between deflection and current, or to a change in the actual sensibility.

These only affect the deflection corresponding to the unbalanced *differences* in the ratios of the coils intercompared so that even if the errors in interpolation should be relatively large, the error in the ratio will be exceedingly small. With the ratios adjusted by means of shunts to within $\frac{100}{1000000}$ of equality an error of 1%, 5 to 10 times that actually existing, would produce an error of one part in 1,000,000 in the calculated ratio of the coils compared.

The Wheatstone-Kelvin bridge entirely eliminates the resistance of the parts connecting the lower mercury cups of these coils by means of shunting a second ratio coil across the resistance to be eliminated, the battery contact being transferred to its middle point. The inequality of the two halves of the ratio coil is eliminated by its reversal. The remaining sources of error are possible variable contact resistances in the mercury cups and possible differences in the insulation resistances between them. The bottoms of the cups are accurately surfaced and these sources of error are shown to have no importance by interchanging the positions of the two coils compared. Thermoelectromotive forces are eliminated by battery reversal. The heating effect of the test current was shown to be quite negligible, less than $\frac{1}{10000000}$ for a current of .03 ampere for one ohm manganin coils, since a current of 1 ampere through such a coil produces a heating of the coil above the temperature of the petroleum bath in which the comparisons are made, of approximately 1°C.

A specimen of the results which may be obtained under rather unfavorable conditions is given below. Four one ohm coils were intercompared in the 6 possible combinations, 6 additional measurements being made with the left and right coils interchanged with the following results:

L R	Observed Differences.	Cal. Diff.	Residuals Obs.-Cal.
L R	1402—1403 = —3.8 × 10^{-6} ohm	—3.8	0.0
R L	1402—1403 = —3.9		—0.1
L R	1402—1404 = —4.6	—3.7	—0.9
R L	1402—1404 = —2.8		+0.9
L R	1402—1405 = —0.8	—0.8	0.0
R L	1402—1405 = —1.0		—0.2
L R	1403—1404 = +0.2	—0.2	+0.4
R L	1403—1404 = —0.6		—0.4
L R	1403—1405 = +3.4	+3.0	+0.4
R L	1403—1405 = +2.5		—0.5
L R	1404—1405 = +3.4	+3.2	+0.2
R L	1404—1405 = +3.0		—0.2

Since resistance comparisons can be made to such a very high order of accuracy, to within $\frac{1}{500}$% at least, even in the case of properly designed .0001 ohm standards, all interested may assure themselves that every effort will be made by the Office to provide itself with primary standards of reference meeting the highest scientific requirements.

STANDARDS OF ELECTRO-MOTIVE FORCE.

The unit of electro-motive force, the volt, is legally defined as $\frac{1000}{1434}$ of the electromotive force of a Clark Standard cell at 15° C.

The official standards of electro-motive force for a government should obviously be, as far as possible, independent of any error due to impurities of the chemicals used. A large number of cells were set up with the purest commercially obtainable materials, from a number of independent sources. The work of purifying these materials by special methods was begun. Cells have also been set up with some of the purified materials, though much still remains to be done.

The intercomparisons so far made indicate a most satisfactory agreement of all the cells on hand, well within $\pm\frac{1}{200}\%$. The mean electro-motive force of the three dozen or more cells furnishes therefore a standard of reference which may be relied on within this limit. In addition to the Clark cells, a number of Cadmium cells, having considerable advantages over Clark cells, have been set up, but owing to lack of time no comparisons have as yet been made. New cells of both types are to be added from time to time, and intercompared with the old ones to determine whether any observable changes have taken place.

The relation which the E. M. F. of the Clark cell bears to that of the Cadmium cell will also be periodically determined, furnishing an additional check on the constancy of the standards of both types.

With an accurately calibrated potentiometer, and reliable standards of electromotive force the office is thus prepared to undertake the verification of direct current volt-meters and millivolt-meters.

MEASUREMENT OF ELECTRIC CURRENTS.

A grave mistake was made by the International Congress in concretely defining all three of the principal electrical units, the ohm, volt and ampere, which are necessarily connected by the fixed relation $C = \frac{E}{R}$. Hence only two of the definitions are independent, the chances being infinitesimal that the three definitions satisfy the relation between them on account of the relatively large errors in the absolute determinations on which they are based. Indeed, it already seems that the volt, as defined in terms of the Clark cell is in error by almost .1%.

Since the standards of resistance and electromotive force, as specified by the International Congress, are certainly reproducible within $\frac{1}{100}\%$, the unit of current intensity, defined as the current which will flow through a conductor of unit resistance, there being unit difference of potential between its terminals, would be fixed within the same limits of error.

Instead, it is defined in terms of the electro-chemical equivalent of silver. The voltametric measurement of a current is limited by the size of the apparatus available and is besides impossible under ordinary circumstances with the above accuracy.

Lord Rayleigh is of the opinion that his determination of the electro-chemical equivalent of silver may be in error by as much as $\frac{1}{10}\%$.

Retaining for the present the legal definitions of the ohm and volt, currents may be consistently measured by the fall in potential or potentiometer method, in terms of the specified standards of reference.

It is proposed to base all direct current measurements on these principles. With suitable low resistance standards for the measurement of heavy currents and with the set of Clark cells already on hand, the Office is prepared to undertake the verification of direct current ammeters within the limits practically set by the current generating apparatus on hand.

To summarize, the Office is therefore practically equipped for the verification of following classes of apparatus, viz:

Resistance Standards.—Coil of the following denominations: 1, 2, 5, 10, 100, 1000, 10,000 ohms.

Low Resistance Standards for current measurements of the following denominations: 0.1, 0.01, 0.001 and 0.0001 ohms.

Resistance boxes.

Potentiometers.

Ratio coils.

Standards of Electro-motive Force.—Clark standard cells and other standard cells.

Direct Current Measuring Apparatus. Millivoltmeters and voltmeters up to 150 volts.

Ammeters up to 50 amperes.

For the verification of direct current measuring apparatus of even moderate range, the present facilities of the Office are entirely inadequate, although now-a-days potential differences up to 20,000 volts and currents of 20,000 amperes are met with in actual practice.

Provision must also be made for the calibration of Wattmeters and Energy meters.

The verification of alternating current measuring apparatus requires further facilities, and in view of the ever increasing importance of alternating current systems, such facilities should be provided without delay.

The verification of Condensers and Self Induction Standards also merits attention.

Another question, practically related to electrical measurements, is the photometry of arc and incandescent lamps.

Preliminary steps have already been taken by the American Institute of Electrical Engineers, looking forward to the coöperation of the office in the official verification of incandescent lamps as secondary photometric standards to enable even the moderate consumer to procure reliable standards at a reasonable rate.

The measurement of high and low temperatures will also be taken up, a knowledge of the exact thermal conditions under which certain industrial operations are conducted being of the utmost practical consequence.

There are two most reliable electrical methods based respectively on the variations of electrical resistance and of thermo-electromotive force with the temperature. Hence, with standards of electromotive force and resistance available, this subject is brought within easy reach.

No claim of originality is made in what has been accomplished. The magnificent work of the Physico-technical Reichsanstalt at Berlin with its staff of scientific and technical assistants and in its almost unlimited resources has been of the greatest help. It has set such a high standard of excellence that it will require years for similar bureaus, which will surely be organized by other governments, to attain.

FRANK A. WOLFF, JR.
U. S. OFFICE OF STANDARD
WEIGHTS AND MEASURES.

THE ESTABLISHMENT OF A NATIONAL UNIVERSITY.*

THE sub-committee appointed November 3, 1899, beg leave to submit the following report:

The resolution of reference to the sub-committee was as follows:

"That a sub-committee be requested to prepare for consideration by the full committee a detailed plan by which students who have taken a baccalaureate degree, or who have had an equivalent training, may have full and systematic advantage of the opportunities for advanced instruction and research which are now or may hereafter be offered by the Government; such a plan to include the coöperation with the Smithsonian Institution of the universities willing to accept a share of the responsibility incident thereto.

"It is understood that the financial administration of this plan should be such that whether or not Government aid be given, there shall be no discouragement of private gifts or bequests.

"It is understood that the scope of this plan should be indicated by the governmental collections and establishments which are now available, or as they may hereafter be increased or developed by the Government for its own purposes."

The undersigned members of the sub-committee have been in active correspondence and conference on the matters referred to them. They have made several visits to Washington, and have had the advantage of hearing the views of representative Regents of the Smithsonian Institution and those of the directors of the scientific bureaus of the Government. In particular, they have profited by consultations with representatives of the American Association of Agricultural Colleges and

* Report of the sub-committee appointed November 3, 1899, to the Committee of the National Educational Association, appointed July 7, 1898, to investigate the entire subject of the establishment of a National University.

Experiment Stations, which body has had before it for some time past a project for the utilization, for graduate students, of the resources of the Departments at Washington.

The sub-committee are of opinion that the general plan of action now under discussion by this committee has secured, and will command, the active support of the directors and administrators of the Government's scientific work as well as that of the educational institutions of the country. It is very generally accepted as the best possible way of meeting what is reasonable in the demand for the establishment of a national university. The success of the plan, however, will depend upon the wisdom with which its details are first formulated and then administered.

Fortunately, the Congress of the United States has already declared it to be the policy of the Government to encourage the use of the scientific collections at Washington by properly qualified students, for purposes of research. This was done by Joint Resolution, April 12, 1892, which reads as follows:

Joint resolution to encourage the establishment and endowment of institutions of learning at the national capital by defining the policy of the Government with reference to the use of its literary and scientific collections by students:

Whereas, large collections illustrative of the various arts and science and facilitating literary and scientific research have been accumulated by the action of Congress through a series of years at the national capital; and

Whereas, it was the original purpose of the Government thereby to promote research and the diffusion of knowledge, and is now the settled policy and present practice of those charged with the care of these collections specially to encourage students who devote their time to the investigation and study of any branch of knowledge by allowing to them all proper use thereof; and

Whereas, it is represented that the enumeration of these facilities and the formal statement of this policy will encourage the establishment and endowment of institutions of learning at the seat of Government, and promote the work of education by attracting students to avail themselves of the advantages aforesaid under the direction of competent instructors: Therefore,

Resolved by the Senate and House of Representatives of the United States of America, in Congress assembled, That the facilities for research and illustration in the following and any other Governmental collections now existing or hereafter to be established in the city of Washington for the promotion of knowledge shall be accessible, under such rules and restrictions as the officers in charge of each collection may prescribe, subject to such authority as is now or may hereafter be permitted by law, to the scientific investigators and to students of any institution of higher education now incorporated or hereafter to be incorporated under the laws of Congress or of the District of Columbia, to wit:

One. Of the Library of Congress.
Two. Of the National Museum.
Three. Of the Patent Office.
Four. Of the Bureau of Education.
Five. Of the Bureau of Ethnology.
Six. Of the Army Medical Museum.
Seven. Of the Department of Agriculture.
Eight. Of the Fish Commission.
Nine. Of the Botanic Gardens.
Ten. Of the Coast and Geodetic Survey.
Eleven. Of the Geological Survey.
Twelve. Of the Naval Observatory.
Approved, April 12, 1892.

The express purpose of this joint resolution is to encourage the foundation of institutions at Washington which may take advantage of the collections and facilities enumerated. This resolution affirms and establishes the principle which must underlie any such plan for a School or Bureau of Research as this Committee now has before it.

The governmental collections and establishments having been declared available for research, the next question is as to the systematic organization of the work to be carried on and the proper oversight of the persons engaged in making investigations. At this point certain practical difficulties must be met.

These collections and establishments are under widely different jurisdictions. Some of them are attached to the Executive Departments, others are independent of any control but that of the Congress. Some of them are adequately equipped and well housed, others are most inadequately provided for. To wait for the reorganization of the scientific work of the Government in systematic fashion, is to postpone indefinitely the question of taking advantage of the opportunites which the Government has to offer. In the view of your sub-committee therefore, it is essential, in any plan which may now be adopted, that no attempt be made to alter the existing status of the Government's scientific work; that is a large undertaking, for which time and further experience are necessary. The conditions at Washington must be accepted just as they are. The head of each Bureau or Division which can offer any facilities for research, should be asked to state, in detail, just what those facilities are, how many persons can be received, and under what limitations or conditions. It would be one of the functions of any administrative officer who might be charged with the oversight of a School or Bureau of Research, to make these facilities known, as well as to exercise supervision over the students who avail themselves of them.

The resolution of reference contemplates the active coöperation of the Smithsonian Institution in the conduct of the proposed School or Bureau. The attitude of the governing board of the Smithsonian towards the undertaking, becomes then a matter of great importance. What this attitude is we are able to learn from the action taken by the Regents of the Smithsonian Institution at their annual meeting, held January 24, 1900, upon a communication from the American Association of Agricultural Colleges and Experiment Stations, which asked for the organization of a Bureau of Graduate Study in Washington under the supervision of the Smithsonian. The report of the committee to which the communication had been referred, contained this language:

"The committee does not hesitate to express its warm and decided sympathy with the general purpose of the movement thus made by the associated colleges. The object sought commends itself to us all, and the zeal and ability with which it has been pressed upon our consideration by the very able and distinguished educators and scientists connected with these colleges furnish ample assurance that the consummation of the great and leading object sought by them is only a question of time. The material already collected in the bureaus and departments of the government furnishes a rich mine of educational wealth that will not be permitted to remain forever undeveloped. This material is now being constantly enriched by the most valuable additions to its present enormous wealth. Already it has invited to the national capital many distinguished scientists, anxious to avail themselves of the superior advantages thus offered for investigation and research.

"Your committee, however, is painfully impressed with the fact that the powers of the Smithsonian Institution as at present organized are scarcely broad enough to embrace the work proposed. And the committee is equally impressed with the fact that even with enlarged authority its present financial condition would absolutely prevent anything like efficient and creditable performance of the work contemplated.

"It is well known to the members of this board that a great wealth of material—material which would be of immense utility in the successful accomplishment of the purposes indicated by the associated colleges—lies buried in the crypts and cellars of the National Museum.

"If our institution is unable for want of room, as it undoubtedly is, even to place this valuable material on exhibition for the public eyes, and as little to arrange it for scientific uses, the problem of providing halls for lectures and meeting the necessary expenditures incident to the work proposed becomes serious and formidable in the extreme. Your committee is not prepared to make definite recommendations to the board for its final or ultimate action. That which is clearly inexpedient to-day may become not only expedient but eminently desirable to-morrow."

It is felt by the Regents of the Smithsonian Institution that their present powers are hardly broad enough to embrace educational work, and also that it is doubtful whether the Congress has power, under the Constitution, to appropriate money, raised by taxation, for purposes of education. In view of the past construction of the 'general welfare' clause of the Constitution, and in view of the fact that the Smithsonian Institution was established 'for the increase and diffusion of knowledge among men,' your sub-committee are unable to share these doubts.

At the same meeting of the Regents of the Smithsonian Institution to which reference has been made, Mr. Alexander Graham Bell introduced the following resolution, which is to be the subject of consideration at a later meeting:

"In order to facilitate the utilization of the government departments for the purposes of research, in pursuance of the policy enunciated by Congress, in a Joint Resolution approved April 12, 1892:

Resolved, That Congress be asked to provide for an Assistant Secretary of the Smithsonian Institution in charge of Research in the Government Departments, whose duty it shall be to ascertain and make known what facilities for Research exist in the Government Departments, and arrange with the heads of departments, and with the officers in charge of Government Collections, rules and regulations under which suitably qualified persons may have access to the Government collections for the purposes of Research, with due regard to the needs and requirements of the work of the Government; and it shall also be his duty to direct the researches of such persons into lines which will promote the interests of the government, and the development of the natural resources, agriculture, manufactures, and commerce of the country, and (generally) promote the progress of science and the useful arts, and the increase and diffusion of knowledge among men."

Should the Regents decide to adopt this resolution, and should the Congress act favorably upon the request which it contains, a Bureau of Research would be established competent to do the work which this committee have in mind.

In this way all of the ends which this committee has deemed desirable, would be accomplished—save one. That one your sub-committee believe to be of the highest importance. It is the co-operation of the universities and colleges of the country in carrying on such systematic research work as is contemplated. That such co-operation should be provided for, by the constitution of an advisory board or in some other way, your sub-commtttee deem essential, not only in the interest of the work itself, but also in that of the universities and colleges. That they would be greatly benefited by the new stimulus which would come from united effort in assisting to conduct such research work as is proposed, is certain.

An alternative plan is worthy of careful consideration. This is to make the Bureau of Education, instead of the Smithsonian Institution, the administrative center of the Bureau of Research. To accomplish this would involve, perhaps, the long-desired erection of the Bureau of Education into a separate department, on a plane with the Department of Labor, and the provision of an appropriate salary for the Commissioner instead of the pittance of $3000 now allowed. The executive head of the Bureau of Research might then be an assistant Commissioner of Education at a salary of $4000 or $4500. One marked advantage of this plan is that the intellectual outlook of the Bureau of Education is likely to be broader than that of the Smithsonian Institution, as the Bureau is in close touch and active correspondence with all the educational institutions of the country, and not merely with those whose main or sole interest is in the field of the natural sciences.

If it is decided that the initiative in this undertaking shall lie with the Regents of the Smithsonian Institution, then your sub-committee are prepared to recommend the following course of action:

1. That the Regents of the Smithsonian Institution be requested to ask the Congress of the United States for a special appropriation for the work of research and investigation, to be conducted under their supervision by persons properly qualified therefor. Such work to be so conducted as to utilize the libraries, scientific collections, apparatus and laboratories owned

by the United States and in charge of officers of the United States, for investigations and researches, under regulations to be prescribed by the said Regents, and as far as shall be mutually agreed upon between the said Regents and the heads of the several executive departments of the Government, the Librarian of Congress, Commissioner of Labor, Commissioner of Fish and Fisheries, and the Secretary of the Smithsonian Institution, with a view of carrying out the policy of Congress, declared in the Joint Resolution of April 12, 1892.

2. That the Regents be requested to ask the general public for gifts of money, to be used in providing buildings, laboratories, equipment and endowments, for purposes of instruction, such instruction to be limited to students who are graduates of properly accredited institutions, or those who are otherwise properly qualified, it being understood that it shall not be the purpose of the Smithsonian Institution to confer degrees of any kind in connection with such instruction.

3. That the Regents be requested to formulate a plan for the appointment of an Advisory Board ; the members of said Board to represent the leading educational institutions of the country, with a view to securing the active co-operation of the colleges and universities of the country in carrying on this undertaking.

If, however, it is decided that the Bureau of Education is the best administrative center for this work, then we recommend the following course of action :

1. That the Congress be requested to erect the Bureau of Education into an independent department, on a plane with the Department of Labor, and to provide a salary of not less than $5000 for the Commissioner of Education

2. That the Congress be requested to provide for an Assistant Commissioner of Education, at a salary of not less than $4000, whose duty it shall be to ascertain and make known what facilities for research exist in the government departments and collections at Washington ; to formulate, in connection with the heads of the several departments and the officers in charge of Government collections, rules and regulations under which suitably qualified persons may undertake research in those departments and collections, with a view to carrying out the policy of Congress as declared in the joint resolution approved April 12, 1892 ; and to exercise general supervision over the persons permitted to undertake such research.

3. That the Department of Education, so organized, be requested to formulate a plan for the appointment of an advisory board, representing the colleges and universities of the country which receive aid from the government or which have not fewer than 25 resident graduate students in any one year, with a view to securing the active co-operation of such colleges and universities in organizing and maintaining the work of research at Washington.

4. That in accordance with a plan to be prepared and adopted by the Department of Education, in consultation with such advisory board or its executive committee, the colleges and universities of the country be asked to give credit, toward the requirements for their higher degrees, for research carried on at Washington under the supervision of the Department of Education.

Under the terms of either of the plans proposed it is assumed that the persons admitted to carry on research will be graduates of a college or university in good standing, or will have had an equivalent training.

Such a bureau of research, whether it be placed under the care of the Smithsonian Institution or under that of the Department of Education—which would supersede the existing Bureau of Education—would be a source of strength to the higher education of the United States and a great advantage to the Government in its work of promoting the progress of science and the useful arts, and in applying the result of scientific investigation to the development of the natural resources of the country, of agriculture, of manufactures, and of commerce.

We regret that our colleague, Dr. J. L. M. Curry, has, through absence from home, been prevented from sharing in the formulation of this report.

Respectfully submitted,

William R. Harper,

Nicholas Murray Butler.

Chicago, Ill.,
Feb. 26, 1900.

ASSOCIATION OF AMERICAN ANATOMISTS.

The Association held its twelfth session December 27 and 28, 1899, at New Haven, Connecticut, in conjunction with the affiliated societies. There were present nineteen members:—Blake, Ferris, Gerrish, Herrick, Holmes, Hrdlicka, Huber, Lamb, Mackenzie, Mall, Mellus, Miller, M. B. Moody, R. O. Moody, Minot, Piersol, Tuttle, Shepherd, and Wilder. New members were elected as follows:—R. Tait Mackenzie, B.A., M.D., Demonstrator of Anatomy, McGill University, Montreal, Canada, No. 59 Metcalfe St., Montreal; E. Linden Mellus, M.D., Fellow in Anatomy, Johns Hopkins University, Baltimore, Md., No. 10 East Chase Street, Baltimore; Wm. S. Miller, M.D., Assistant Professor of Vertebrate Anatomy, Wisconsin University, Madison, Wisconsin, 615 Lake Street, Madison; Alexander Primrose, M.B.C.M. (Edin.), M.R.C.S. (Eng.), Professor of Anatomy, University of Toronto, Canada, 100 College Street, Toronto; Richard Dresser Small, A.B, M.D., Instructor in Anatomy, Portland School for Medical Instruction, 606 Congress Street, Portland, Maine. Dr. John Cleland of Glasgow, Scotland, was elected an honorary member. Dr. Frank Baker resigned from the Committee on Anatomical Nomenclature and Dr. H. B. Ferris was appointed to fill the vacancy. The annual dues were increased to five dollars. It was decided to meet as usual with the Congress of American Physicians and Surgeons this spring. The Association voted that members desiring to subscribe for the *Journal of Anatomy and Physiology* could do so through its Secretary at net cost of $5.30; also that the titles of papers to be read at meetings should be accompanied by abstracts of about 150 words each. Officers for the ensuing term were elected:—Dr. George S. Huntington, New York City, President; Dr. F. H. Gerrish, Portland, Me., First Vice-President; Dr. G. C. Huber, University of Michigan, Second Vice-President; Dr. D. S. Lamb, Washington, Secretary and Treasurer; Dr. C. S. Minot, of Boston, member of the Executive Committee in place of Dr. Gerrish, retired.

In the absence of Drs. Huntington and Spitzka, the Committee on Anatomical Nomenclature (Drs. Gerrish, Wilder and Ferris) reported progress and asked the Association to consider, with a view to decisive action at the next session, the following names for constituents of the peripheral nervous system. Where a single term is given it is the one adopted by the B. N. A., and also preferred unanimously by the Committee. Where two terms are used the first is the one in the B. N. A., but this does not imply that it is preferred by the Committee.

Nervi cerebrales vel craniales.

Nervi olfactorii,
Nervus opticus,
" oculomotorius,

Ganglia trunci sympathici,
Plexus sympathici,
Ganglia plexuum sympathicorum.

The address of the President, Dr. Wilder, was entitled, 'Historic, ethical and practical considerations respecting the names and numbers of the definitive encephalic segments.' There were presented facts and arguments in favor of maintaining the customary method of enumerating the segments of the brain beginning with the most cephalic or 'anterior,' and in favor of retaining for five of these segments the names, *prosencephalon*, *diencephalon*, *mesencephalon*, *epencephalon* and *metencephalon*, which were adopted or proposed in 1867 by the editors of the seventh edition of 'Quain's Anatomy.' In particular it was shown that the replacement of *metencephalon* by 'myelencephalon' for the last (oblongatal) segment, as done by Huxley and in the B. N. A., is not only unjustifiable on historic and ethical grounds, but practically objectionable because it apparently involves the retention of the lengthy and unrelated terms of the B. N. A., viz: 'myelencephalon,' 'ventriculus quartus,' 'tela chorioidea ventriculi quarti,' 'plexus chorioideus ventriculi quarti,' and 'apertura medialis ventriculi quarti' (foramen Magendii), and the abandonment of the series of correlated single-word terms, *metencephalon*, *metacoelia*, *metatela*, *metaplexus* and *metaporus*. (The address will be published in SCIENCE.)

The following papers were read:

Divisions of cranial bones in man and animals: DR. ALES HRDLICKA, of New York City.

Five classes of divisions are described and demonstrated, namely: (1) results of fractures; (2) normal, partial divisions in definite locations in the bones of the embryos and new-born; (3) anomalous partial divisions consequent upon the formation of a foramen in the ossifying bone; (4) divisions due to a retardation of the union of any of the normal segments of the bones; and (5) anomalous divisions due to an abnormal multiplicity of the centers of ossification. Class (2):—Two of the most prominent and constant of such divisions in man are the parietal incisure of Broca, and a squamous suture situated near the middle of the occipital border of the parietal bone (termed 'parietal suture' by the author). Class (3):—Rare in man, so far as the bones of the cranial vault are concerned, but are common in the human superior maxillæ in connection with the infraorbital foramen; they are very frequent in the parietal and temporal bones in mammals, particularly in the herbivora. Class (5):—Occur generally in the form of sutures dividing the whole bone or separating one of its angles. They are liable to be confounded with the previous and are somewhat allied to the same. These divisions are well known in the human parietal; the author has the records of eighteen new cases, found principally in macaques; one of the specimens presented before the Association shows a bilateral division of the parietal bone in a chimpanzee. In lower mammals these divisions are extremely rare.

A further contribution to the study of the tibia, relative to its shapes (vide last year's Proceedings of the Association): DR. ALES HRDLICKA.

An effort has been made during 1899 to learn the occupations of the subjects whose tibias had been examined. The returns show a great diversity of occupations and even of classes of occupations, and it is plain that if any definite conclusions are to be reached, the investigations must extend over at least another thousand of subjects. The main indications so far are as follows: Inactivity of the lower extremities favors the persistence of the adolescent shape of the tibiæ; considerable activity in the lower limbs especially if of a definite kind, favors a differentiation in the shape of the bones. In the American Indians who were always great walkers and did otherwise comparatively but little, types two and four of tibiæ prevail. In strong, but also in rachitic, individuals there is an inclination to type 3 of the bones. There was but little occasion to inquire into the influence of heredity on the shape of the tibiæ, nevertheless such influence seems very probable.

The deep fascia: DR. HOLMES, University of Pennsylvania.

The deep fascia is a firm tense membrane of wide extent and complex function. It lines the interior of the abdomen, protects the various orifices, forms ligaments for the organs and a floor for the pelvis, sheathes vessels and muscles and binds muscles into groups, divides regions into spaces and sets off organs by themselves, so that differentiation into fascial compartments means also differentiation into function. The transversalis fascia is a continuation of the fascia-lata and forms a fibrous bag for the abdomen continuous posteriorly with the lumbar fascia. It is the real pelvic floor rather than the levator ani muscle. The subdivisions of the muscles of the thigh, leg and foot, and of the axilla, arm, forearm and hand indicate the separate office of each group. In the cervical region the three divisions of investing, pretracheal, and prevertebral, indicate similar conditions; the prevertebral layer being of especial value in conserving the action of the esophagus, larynx and trachea. The especial object of the paper is to direct the attention of the members of the Association to the greater importance of the fascia, and also to maintain that whenever we find its distribution separating the structures, we may regard it as an indication of an equal separation into a distinct function.

The facial expression of fatigue and violent effort: DR. R. TAIT MCKENZIE, McGill University.

In fatigue, as observed in a foot-race of a mile, we see the following changes: The lips are slightly parted, the teeth open, eyes semi-closed, brows contracted, as in mental concentration, the upper half of the orbicularis acting with the corrugator supercilii. As the race proceeds, the lips are drawn down by the depressors and up by the levator proprius and zygomaticus minor. The corrugator acts strongly. As the respiratory need increases, the nostrils are dilated by the levator labii superioris alæque nasi, accentuating the expression of grief. This expression then passes away and the face becomes apathetic, the mouth gapes and the jaw drops, the upper eyelid tends to droop. The lowering of the upper lid is counteracted either by throwing the head back, or by bringing into action the occipito-frontalis. This give rise to an expression of astonishment in the upper part of the face. In extreme exhaustion or collapse, the jaw drops, the upper lid comes down, the face becomes expressionless. When a violent effort is made the expression comes more nearly to correspond to rage.

A note on the relation of the external carotid artery: DR. WM. KEILLER, of Texas.

Text-book descriptions of the relation of the external carotid (with the exception of Cunningham's description in his 'Dissector's Guide') are incorrect: (1) In describing the ramus of the jaw as an internal relation when it is really external. (2) The structures described in text-books as lying in front are really external. (3) The statements as to its relations to the parotid gland are misleading. (4) It is at first anterior, and slightly internal to the internal carotid, then winds backwards and outwards till it lies on its outer side. (5) Most of the structures described as lying behind it are internal.

How best to teach anatomy to the third year medical students: DR. KEILLER.

Brief sketch of a course of dissections of direct surgical and medical interest, and leading up to an operative course, being the third year's course of practical anatomy at the University of Texas.

The anatomy of the anal region : DR. KEILLER.

Careful description of the relations of the levator ani, external and internal sphincter, the radicles of the hemorrhoidal veins, and the bearing of these facts on operations for piles and on the pathology of ischiorectal abscess.

On a hitherto unrecognized form of vertebrate blood circulation in organs without capillaries: DR. MINOT, Boston.

Non-development of the left heart and closure of the aortic valve, depending upon an error in the development of the auricular septum : DR. BLAKE, New York City.

The child from which the specimen was taken lived four days. It presented no other abnormalities. It was cyanotic and died of cardiac failure. The right chambers of heart, the pulmonary artery and ductus arteriosus are very large. The left chambers are very small. The aortic opening is closed by a fibrous septum consisting of the fused valves. The ascending aorta is only of sufficient caliber to supply the coronary arteries. The eustachian valve is rudimentary.

The valve of the foramen ovale is developed in the right auricle so that fluids can only pass from the left to the right auricle. This arrangement of the valve can be explained by the method of development of the auricular septum, as described by Born in rabbit embryos, if we presume an overgrowth of the septum secundum and an insufficient development of the primary septum. The interest of the specimen lies in the generalization of the application of Born's theory of development. The left ventricle receiving no blood, the aortic valves were kept closed by back pressure and fused. No similar anomalies could be found recorded.

The delimitation of the divisions of the large intestine according to intrinsic features : DR. GERRISH.

The argument made is that the segment variously called sigmoid colon, sigmoid flexure, iliac colon, and omega flexure, should include all of that part and only that part of the large intestine, caudad of the crest of the ilium, which has a mesentery. This plan would subtract a little from the cephalic portion of the sigmoid colon, as generally accepted now, and would add to its caudal portion making the rectum begin at the third sacral vertebra.

The normal capacity of the human bladder : DR. GERRISH.

This question can be answered by physiologic tests only. The normal capacity is not shown by the amount of fluid which the viscus can possibly contain without rupture or even by that which it occasionally holds without appreciable harm. But it can be determined by ascertaining the average amount of urine secreted in 24 hours and the average number of micturitions in the same time. By this method the capacity is found to be not much in excess of 250 grams (8 oz.) : one-half that usually stated.

Observations on sensory nerve fibers in the visceral nerves, with remarks on their mode of termination : DR. HUBER.

That relatively large medullated nerves end in the viscera we know from the observations of Gaskell, Langley and Edgeworth, and from the more recent investigations of numerous observers who have investigated the sympathetic nervous system or the innervation of the viscera with the aid of the Golgi or methylin blue methods. That these relatively large medullated nerves terminate either in special end-organs, Pacinian corpuscles, encapsulated nerve-endings of Timofew, etc., or in free sensory endings, seems also well established. The writer proposes to draw attention more especially to the free sensory endings in viscera, and to emphasize the following points: (1) the repeated division of such sensory nerves before losing their medullary sheaths; (2) the relatively large number of arborizations in which such nerves terminate; and (3) the fact that they terminate in the mucosa and epithelium lining the hollow organs and ducts.

Sensory nerve terminations in the tendons of the extrinsic eye muscles of the cat: DR. HUBER.

Marchi, Ciaccio and Sherrington have shown that medullated nerve fibers terminate in the tendons of the extrinsic eye muscles of a number of mammals. These nerves are looked upon as sensory nerves, although, as Sherrington has shown, not branches of the ophthalmic division of the trigeminus. In the cat the nerves ending in the tendons of the extrinsic eye muscles do so in terminations which differ in structure from the neuro-tendinous endings found in other skeletal muscles of this animal. The medullary nerves which terminate in the eye muscles of the cat lose their medullary sheaths just before reaching their destination and end in a network of varicose fibers, which network surrounds the tendon fasciculi just distal to the insertion of the muscle fibers. Each tendon fasciculus surrounded by such a plexus is enclosed within a thin, closely fitting, fibrous sheath.

Comments upon the figure of the mesal (median) aspect of a human brain as published by His and reproduced by him and others: DR. WILDER.

"In the *Archiv für Anatomie* for 1893, Professor His published a figure of the mesal aspect of an adult human brain; it was reproduced on p. 76 of the protocols of the B. N. A., and in the B. N. A. itself, *Archiv für Anat.*, 1895, Suppl. Band., p. 161, but is there stated (evidently through inadvertence) to represent a fetal brain of the third month. The figure has been reproduced without comment by Van Gehuchten (second edition) and Barker ('The Nervous System,' 1899, Fig. 92). Even if designed merely as a diagram in illustration of its author's views of the definitive segments, and even if many teachers and investigators are so well informed as not to be misled by its errors of omission and commission, certain features are certain to cause serious and wide-spread misapprehension. Twenty such features were specified. The most important exemplify the general defect of such figures in most manuals, viz., incomplete circumscription of the cavities, and inadequate demarcation of the cut surfaces from the natural (pial or endymal). In these respects anatomists may well imitate the accuracy of Reichert ('Der Bau des menschlichen Gehirns,' 1859–61), although his figures are not absolutely perfect.

If an 'Isthmus Rhombencephali' why not an 'Isthmus Prosencephali'? DR. STROUD, Cornell University.

"In the early fetal brain of man, the cat, and perhaps some other mammals, there is a necklike region just caudad of the mesencephal. Professor Wilhelm His names this region 'Isthmus Rhombencephali,' and apparently regards it as coördinate with the other five definitive segments recognized by him (*Archiv. für Anatomie,* 1893, 173–174; 1895, Suppl. Bd. 'B. N. A.,' 157). But in these same specimens, and in many of the figures published by His in the *Archiv* for 1892 and 1893, and in 'Die Entwickelung des menschlichen Rautenhirns,' 1891, there is another necklike region cephalad of the mesencephal quite as distinct and sometimes more so. A schema of encephalic segmentation should be consistent, and while not denying the possibility that one or both of these regions may represent a primitive neuromere, it seems reasonable to conclude that, taking into account the adult and developmental conditions in vertebrates generally, probably neither should be regarded as a definitive segment.

The basis and nature of a schema of the definitive encephalic segments: Dr. Wilder.

"A satisfactory definition of 'Definitive Encephalic Segment' has not yet been framed, but the best example is the Mesencephalon (crura and quadrigeminum). Although developed from one 'vesicle,' this apparently includes at least two of the 'neuromeres or primitive segments.' Many points are still undetermined. Some were discussed in 1897 in 'What is the Morphologic Status of the Olfactory Portion of the Brain?' Others are indicated among the fifty 'Questions as to the Segmental Constitution of the Brain'; copies of the seven mimeographed sheets bearing these 'questions' were distributed at the meeting and will be sent to those interested. The following conclusions are regarded as sound:—The provisional schema of the definitive segments should be based upon adult rather than developmental conditions. The definitive segments need not be structurally or developmentally identical. They need not coincide with either, (*a*) the primitive neuromeres, or (*b*) the primary encephalic vesicles, (*c*) the secondary vesicles. No species or group should be ignored. The presumption is in favor of generalized forms, and not in favor of forms merely because they are available for other purposes. When both naturalness and convenience are taken into account, the best provisional schema corresponds mainly with the one indicated in the table on p. 29 of the Proceedings of this Association for May, 1897."

Is neuron available as a designation of the central nervous system? Dr. Wilder.

"Neuron (from τό νεῦρον) was proposed by me in this sense in 1884 (*N. Y. Med. Jour.*, Aug. 2, p. 114), and employed in the same Journal, March 28, 1885, p. 356; in addresses before the Amer. Neurol. Assoc.; (*Jour. Nerv. and Ment. Dis.*, July, 1885); *Amer. Asso. Adv. Sci. Proceedings*, 1885, and in the second edition of 'Anatomical Technology,' 1886. It has been adopted by McClure, Minot, Waters and others. The reasons for its abandonment in 1889 for *neuraxis*, as stated in the Proceedings of this Association for 1895, p. 44, and Ref. Handbook of Med. Sci., IX., 100, now seem to me inadequate. *Neuron* is the basis of *neural* (as applied to aspect, folds, furrow, and canal) and of *neurenteric* and other compounds, and it is the natural correlative of *enteron* (entire alimentary canal) and of *axon* (notochord or primitive skeletal axis). Not until 1891 did Waldeyer propose *neuron* for the nerve-cell and its processes; not until 1893 did Shafer apply it to the axis-cylinder process. As with *tarsus* and *cilium* the context would commonly avert confusion between the macroscopic and microscopic significations of the word in a given case. The compounds *macroneuron* and *microneuron* might be employed if necessary, or (as suggested by Barker, p. 40), the histologic element might be designated by *neurōne*, as if from νευρών. Note.—The question is now further complicated by Van Gehuchten's adoption of 'Neuraxe' as the title of a new journal of neurology.

Polydactylism and Syndactylism: Dr. Shepherd, of Montreal.

Dr. Shepherd showed a series of skiagrams and photographs illustrating some of the deformities of the digits which he had met with. The first case was that of a young man aged 21, who had six digits on each foot and hand, and they were so arranged that the deformity would not be noticed unless attention was especially attracted to it; there was a gradual diminution in the size from the middle finger to the supernumerary little digit (post minimus). His paternal greatgrandfather had supernumerary digits, as had a paternal uncle, and this uncle's children had supernumerary digits. Two of his own brothers and two of his sisters had a like conditions as well as his sisters' and brothers' children. In another case also there was a hereditary history for some generations on the father's side. Another case was stated and the photographs shown where, in a man aged 22, there was no thumb on the left hand and only a very rudimentary one on the right hand; no history of heredity. Another, where there was absence of the thumb of right hand and a rudimentary little finger with absence of the fifth metacarpal bone. The father had a similar deformity. A remarkable skiagram was exhibited which showed a fusion anteriorly of the proximal phalanges of the middle and ring fingers, and a complete fusion of the middle and distal phalanges of these fingers; also a case of fusion of the ring and middle fingers of the right hand in a boy age 20. In neither case was there any history of heredity. In the case of polydactylism, Dr. Shepherd thought some of the cases might be due to reversion, but the majority he thought were probably the result of dichotomy.

Secretary.

SCIENTIFIC BOOKS.

Kongl. Svenska Vetenskaps-Akadamiens Handlingar, Bandet 31. No. 5. Rhopalocera Æthiopica. Die Tagfalter des Æthiopischen Faunengebietes. Eine Systematisch-Geographische Studie. CHR. AURIVILLIUS. Pp. 571. Six chromo-lithographic plates containing 50 figures. Numerous figures in the text. Large 4to. Stockholm, 1898.

Without the aid which learned societies are sometimes able to supply, important works, like the Rhopalocera Æthiopica of Professor Aurivillius, would not often see the light. The demand for such treatises is restricted, being largely confined to specialists, and the expense of producing them is necessarily very great. For many years the learned author has been gathering the material for his undertaking, which having been completed, was laid before the Royal Academy of Sciences in Stockholm on the 10th of June, 1898. The work was issued from the press in June of 1899.

After a brief introduction the author defines the limits and subdivisions of the Ethiopian Region, closely following Wallace, Sclater and others, and excluding the regions immediately bordering upon the Mediterranean from consideration, because the fauna of the northern coast-lands is distinctly palæarctic, and including southern Arabia, the tropical islands, and Madagascar.

This chapter is followed by a bibliography of the subject, arranged according to the political subdivisions of the region. The list of books and papers, while extensive, is, nevertheless, not as complete as might be desired, a number of titles having been apparently overlooked in preparing the bibliography, although in most cases they are subsequently referred to in the text.

The systematic position of the Rhopalocera is next discussed. The author follows Haase and E. Reuter in excluding the Hesperiidæ from the Rhopalocera, regarding them as an independent group, the *Grypocera*, of equal value with the butterflies, and intermediate between them and the moths, or Heterocera. In this view, he will probably find few followers, although a good deal may be said in favor of such a procedure. The Hesperiidæ are accordingly excluded from consideration in the treatise, which enumerates sixteen hundred and thirteen species of Rhopalocera, in this restricted sense, as occurring in the Ethiopian region. Of these species thirty-three, or 2.04 per centum of the whole, also occur in other faunal regions. If we include the Hesperiidæ enumerated by the present writer in his 'Synonymic Catalogue of the Hesperiidæ of Africa and the Adjacent Islands,' published in the Proceedings of the Zoological Society of London in 1896, to which some twenty or more species, described since then must be added, we have a total of nineteen hundred and eighty, or, in round numbers, two thousand species of Rhopalocera in the usually accepted sense of the term occurring in the Ethiopian region. Further explorations are likely to bring to light many species as yet unknown, and the student who is familiar with the subject will see that this is from the standpoint of the lepidopterist one of the richest regions on the globe, the number of species greatly exceeding that represented by the butterfly-faunæ of the Palæarctic and Nearctic regions combined. In extra-tropical North America there occur about six hundred and fifty species, and in Europe and extra-tropical Asia together not more than seven hundred species all told.

A chapter is devoted to terminology. The author's views as to what properly constitutes a generic name are clear, logical, and forcibly expressed. He rejects as *nomina nuda* the generic terms employed in Hübner's 'Tentamen,' Billberg's 'Enumeratio,' and other "equally worthless publications, which have been regarded as establishing priority for a name, although these names are unaccompanied by any description of the genus, and are only applied to one, or at most several species."

The bulk of the work, four hundred and sixty-three pages, is taken up in presenting a Synonymic Catalogue of the species, keys to the various families, subfamilies, and genera being provided. This portion of the work cannot fail to be exceedingly useful to the student, and may in general be said to be very well done. Here and there errors are discoverable, owing to the fact that the author did not have access to the types of some of the species which he enumerates. It is not, however, the purpose of the writer in the present brief review to point out these occasional blemishes, as attention would be more properly called to them in a journal specifically devoted to entomology.

The concluding portion of the text, pp. 493–537, is devoted to a discussion of facts relating to the distribution of species in the various zoögeographical subregions of the Ethiopian territory, and the relationship of the butterfly-fauna of Africa to the lepidoptera of other portions of the earth, followed by some observations upon seasonal dimorphism and protective mimicry. This is to the general student the most interesting part of the entire treatise, and brings into light some highly interesting facts.

The Ethiopian butterfly-fauna includes one hundred and twenty-eight genera, of which eighty-six, or nearly 68 per cent. are peculiar to this region. Of the forty-two genera, which occur in the other regions of the earth, eight, *Danais*, *Pyrameis*, *Libythea*, *Cupido*, *Heodes* (*Chrysophanus*, *Auctorem*), *Pieris*, *Colias*, and *Papilio* are more or less cosmopolitan, while *Acraea* (sens. lat.), *Catopsilia* (sens. lat.), and *Terias* are common to the tropics and sub-tropics of both hemispheres. Of the remaining thirty-one genera which the Ethiopian region possesses in common with other regions, twenty occur in the Indo-malayan, and to some extent also in the Austro-malayan Regions, but are altogether wanting in the Palæacrtic region. These genera are *Euplœa*, *Elymnias*, *Melanitis*, *Henotesia*, *Atella*, *Salamis*, *Hypolimnas*, *Kallima*, *Eurytela*, *Ergolis*, *Biblia*, *Cyrestis*, *Abisara*, *Deudorix*, *Hypolycæna*, *Spalgis*, *Lycænesthes*, *Leptosia*, *Appias*, and *Eronia*. The genera *Yphthima*, *Precis*, *Charaxes*, *Spindasis*, and *Teracolus* are Indo-malayan, although they are represented by one or other species in the extreme southern portion of the Palæarctic Region. *Argynnis* and *Neptis* are well represented in the Palæarctic and Indo-malayan Regions, *Pararge*, *Brenthis* and *Phyllocharis* are to be classed as Palæarctic genera, though they are represented in the northernmost portion of the Indo-malayan Region, and *Brenthis* is found in North America, and extends along the western Cordilleras to the extreme southern end of the continent of South America. The only remaining genus, *Hypanartia*, is peculiar to Africa and the tropical and subtropical regions of the Western Hemisphere.

Of the forty-two genera which Africa possesses in common with other regions, all except the three palæarctic genera and *Hypanartia* are found in the Indo-malayan region. Whether they migrated from Asia into Africa or from Africa into Asia cannot well be determined, but that, if such migration occurred, it must have been at a time when climatic and other conditions were widely different from what they now are, is plain. A wide barrier of sea and arid lands devoid of suitable vegetation separates at the present time the regions in which these insects, for the most part forest-loving, occur. The sandy wastes of Arabia and the rocky plateaus of Abyssinia are a great and impassable barrier, to say nothing of the Indian Ocean, to the transfer of genera which frequent the hot and dense forests of tropical West Africa and the equally hot and heavily timbered lowlands of India and the Malay archipelago. In Arabia, the present dividing region, many of these genera are altogether wanting.

Pararge and *Phyllocharis*, palæarctic genera, may have entered the region in which they now occur by migration along the Nile. It is quite different with the genus *Brenthis*, which occurs isolated upon the slopes of Kenia, Kilimanjaro, and Ruwenzori, the lofty volcanic peaks which dominate the plains of eastern and southeastern Africa. The nearest locality in which this genus finds representation at the present time is in the Alps of Switzerland, the Himalayas in India, and the Andean region of Patagonia. That the genus *Brenthis* should occur on the lofty summits of the East-African mountains and be there as the result of a migration from Switzerland, the Himalayas, or Patagonia, under conditions such as exist at the present time, is an untenable hypothesis, which no student would venture to advocate. The occurrence of *Hypanartia* only in Africa and South America, and the existence in Africa of the genus *Crenis*, so closely related to the South American genus *Eunica*, as scarcely to be separable from it, are facts pointing strongly to the existence in some remote time of a land connection between the continents of Africa and South America. Correlated with the facts as to the distribution of these genera of butterflies is the fact that in the avifauna of Africa and South America we find the *Struthionidæ*, or ostriches represented in both localities, and the species of the genus *Rhipsalis*, of the Opuntieæ occurring in the Cameroons and Madagascar, are witnesses in the floral world to the ancient bond between two now widely separated continents. To these facts cited by our author the writer may add the fact that in the elder groups of the arthropoda, as for example the Phrynidæ, similar instances of the occurrence of closely related forms in Africa and tropical America occur. These things all go to confirm the view which is coming to be generally held by geologists and paleontologists upon apparently strong and sufficient grounds, that in the mesozoic and elder tertiary, a union between the Eastern and Western Hemispheres existed by means of an Antarctic continent, which has largely disappeared, but which at that time, in some way united Africa and Madagascar, and very probably likewise Australia, to the land-mass now known as South America.

Under the head of 'Mimicry' the author gives a list of forty-nine species which are mimicked and sixty-six species which mimick them. It is very doubtful whether this list is correct in representing certain species as mimes, especially where a species of *Terias* is represented as mimicking a *Pieris*, or a *Catopsilia* the female of *Teracolus*. The cases cited, with which the present writer is very familiar, do not come under the head of 'protective mimicry' at all, but fall into the common category of general resemblance or family likenesses. This part of the work, while interesting, gives evidence of less care in preparation and less familiarity with essential facts than any other part of the work.

Upon the whole the student of African entomology has great reason to be grateful to Professor Aurivillius for having had the patience and zeal to prepare this monumental volume, which must for years to come serve as a key for unlocking the treasures of knowledge as to the butterfly-fauna of the Dark Continent.

W. J. HOLLAND.

WESTERN UNIVERSITY OF PENNSYLVANIA,
February 24, 1900.

Zoological Results based on Material from New Britain, New Guinea, Loyalty Islands and elsewhere, collected during the years 1895, 1896 and 1897, by Arthur Willey. Cambridge, Eng., the University Press. 4to. Part III., May, 1899; pp. 207–356; plates XXIV.–XXXIII.

Part III. of Dr. Willey's 'Zoological Results' opens with an account by Gadow of the variations in the number and arrangement of the scutes on the carapace of the loggerhead turtle. The material consisted in part of twenty specimens of new-born loggerheads all taken from one nest in New Britain and all showing abnormal numbers of scutes. This was supplemented by fifty-six other specimens from various collections, making in all a total of seventy-six individuals examined. The typical arrangement of the scutes on the loggerhead is as follows: The chief axis of the carapace is covered by six median elements; these are flanked by five pairs of costals; and the edges of the carapace are bounded by thirteen pairs of marginals. In studying the variation of these parts, Gadow has confined his attention to the median and costal elements. The variations in these series took the form of supernumerary scutes. Thus the total number of median elements may rise from six to seven or eight, and of costal elements on a given side from five, to six, seven, or even eight. In the costal scutes the variations were in some instances symmetrical, in others unsymmetrical. It will be observed that all these variations lie above the normal, and, as there is reason for believing that primitive turtles had a greater number of scutes than modern ones, Gadow holds that these variations are to be interpreted as atavistic. According to his belief, the ancestral turtles possessed at least eight median and eight pairs of costal plates. The reduction of these by which the condition in the loggerhead was reached, as indicated by the variations observed, was as follows: Of the original eight median scutes, the seventh was probably the first to disappear, followed by the fifth, thus giving rise to the series of six, typical for the loggerhead; of the original eight pairs of costals, the second pair was probably first lost, then the fifth and, by the fusion of the seventh and eighth, the condition of five pairs characteristic for this species was reached. For variations of this atavistic kind, Gadow, without further comment, proposes the term orthogenetic, a rather summary procedure in our opinion, since this term has already been extensively employed by Eimer for a different phenomenon. More or less looseness, however, pervades the whole paper and appears strikingly in the diagrammatic figures VII. and VIII. (p. 217), which, though intended to make the subject clear, really lead to confusion from the fact that the system of cross-hatching adopted is incorrectly used. It is to be regretted that a little more care was not exercised in the preparation of what is otherwise an interesting and valuable contribution.

The second paper in this part is by Dr. Willey himself and deals with the South Pacific and West Indian Enteropneusta. To the five species of these worm-like animals previously known from the region in which Dr. Willey collected, three new species are added. Two other new species from the West Indies are also described. The paper contains a synopsis of the families and genera of the Enteropneusta and a full description of the new species. These organisms are of importance because of their supposed relation to vertebrates, and the concluding part of Willey's paper deals with their morphology from this standpoint. A comparison of the central nervous organs, of the supporting axis of the body, of tubules kidney-like in character, and of the gills in the Enteropneusta, the tunicates, and the vertebrates confirm the belief in the natural affinities of these three groups of animals. In the course of this discussion the author suggests the novel idea that the genital glands and gill-slits were primarily unlimited in number and coextensive in distribution, and that the primary function of the gill-slits was the oxygenation of the genital glands, their secondary function being the respiration of the individual.

The concluding paper is by Shipley and deals with the five species of Echinoids collected by Willey. A revision of this group of worms is given together with an account of their geographical distribution.

G. H. Parker.

Minnesota Plant Life. By Conway MacMillan. Report of the Survey; Botanical Series, III. St. Paul, Minnesota, October 30, 1899. Octavo, 568 pages.

This is probably the most remarkable State report ever published. The author has given to the world a thoroughly scientific treatise, which is a contribution to our knowledge of the flora of Minnesota, and yet he has done so in such a way that, at the same time, the volume is one of the most popular of the State reports. This fact alone would mark the book as one of the most notable of recent publications, but when we add the beauty of its typography and illustrations, excellence of paper, and perfection of printing, so generally wanting in State Reports, we are doubly surprised. It is encouraging to find an author, who is an acknowledged master of the vocabulary of technical science, who here shows that he is equally at home in the non-technical presentation of strictly scientific facts in a somewhat new field of botany, and to learn that even State printing may be brought to compete successfully with the finest work done in private establishments. This volume is thus a distinct gain along more than one line.

The purpose of the book cannot be told better than in the author's own words: "In the pages of this book I hope to give the reader an idea of the diversified plant life which occupies the air, the soil and the waters of Minnesota. First of all, it must be remembered that plants, although passive creatures, are quite as truly living beings as are the more active animals. Just as men and women, either themselves or their ancestors, have entered the state from some other region, so also have plants, according to the nature of each, found their way and selected their abodes. It is no easy problem to determine why some family has chosen one village rather than another. This may have been from causes which are too subtle or too remote for analysis, but it is recognized that people have not come to make their homes without some reason which seemed sufficient to them or to their forefathers. So, too, there is always some reason for the appearance at a particular spot of one kind of plant rather than another, and it is possible, in a general way, to explain the vegetation of the hills and meadows of the state" (page 1).

Then follow simple discussions of the geography, climate and physical history of Minnesota, the laws of plant distribution, plant zones, the forests of Minnesota and the world, the North American flora, plant wanderings and migrations, associations between migrating plants, struggles of migrating plants, etc.

In speaking of the number of species of plants, the author estimates that of the 300,000 now living, about 7500 are probably to be found growing without cultivation in Minnesota, and distributes them approximately as follows: Slime moulds (which later he says are 'more probably animals') 150; bacteria and algæ, 1000; fungi and lichens, 3250; liverworts and mosses, 500; ferns and flowering plants, 2600.

Thirty-seven chapters are given to a general account of the vegetation of the State, under such heads as 'Slime Moulds and Blue-green Algae,' 'The lower sorts of Fungi,' 'Carrion-Fungi and Puff-balls,' 'Lichens and Beetle-fungi,' 'Mosses and Liverworts,' 'Ferns and Water-ferns,' 'Ground-hemlocks and various Pines,' 'Grasses and Sedges,' 'Poplars and Willows,' 'Roses, Peas and their Relatives,' 'Wintergreens to Chaffweeds,' 'Peppermints to Plantains,' 'Dandelions, Ragweeds and Thistles.'

The remaining chapters (XL. to XLV.) are devoted to a general discussion of the ecological problems involved in a full understanding of the flora. One of these takes up 'Adaptations of Plants to their Surroundings,' in which the several factors, Gravity, Mechanical Forces, Heat, Light, Moisture, Electricity and Magnetism, the Soil or Substratum, Other Living Things, and Intra-specific Adaptations are discussed. Another is given to Hydrophytic Plants, another to Xerophytic Plants, and still another to Halophytes and Mesophytes. These chapters, in spite of their titles, are very simply treated, and may be read easily by any person of average ability. The closing chapters are more philosophical and are devoted to the Maintenance of the Plant Individual, and the Maintenance of the Plant Species.

The author has certainly succeeded "in portraying the vegetation of Minnesota as an assemblage of living creatures, as a world of infinite variety, yet with a fundamental unity of plan, as forms linked together in structure, function and adaptation," and he has done so in language so simple, and yet so precise as to afford to us a new suggestion as to the presentation of scientific matter for the public. There is here left no opportunity for the shallow book-writer to take the author's results and work them over into more popular form, with the inevitable errors, inaccuracies and misrepresentations which characterize such productions. Professor MacMillan has wisely chosen to supply his own popular edition.

Charles E. Bessey.

The University of Nebraska.

SCIENTIFIC JOURNALS AND ARTICLES.

The American Naturalist for February has for its first article a paper by Henry Fairfield Osborn on 'The Angulation of the Limbs of Proboscidia, Dinocerata and other Quadrupeds in Adaptation to Weight.' Stephen R. Williams discusses 'The Specific Gravity of some Fresh Water Animals in Relation to their Habits, Development and Composition,' the conclusion being that the movements of an animal are closely related to its density and this in turn to its food habits. Carl H. Eigenmann and George Daniel Shafer describe 'The Mosaic of Single and Twin Cones in the Retina of Fishes,' Thomas H. Montgomery has a 'Note on the Genital Organs of Zaitha,' and Maynard M. Metcalf in 'Willey on the Enteropneusta' directs attention to some of that author's far-reaching theoretical conclusions. The 'Synopses of North American Invertebrates' are again continued, Mary J. Rathbun contributing the seventh part on the Cyclometopous or Cancroid Crabs. The balance of the number is occupied with reviews of recent literature.

In *The Osprey* for February, Paul Bartsch continues his 'Birds of the Road,' and under 'Esthetic Birds' is given Beccari's account of the Gardener Bird of New Guinea. Eugene S. Rolfe presents 'Nesting Notes on the Waders of the Devil's Lake Region,' and W. E. Clyde Todd has an excellent article on 'The Requirements of a Faunal List,' while Philo W. Smith, Jr., describes the 'Nesting of Stephen's Whip-poor-will.' The editor contributes some valuable comments on 'The Origin of the Hawaiian Fauna,' and there are some interesting letters and notes.

The *Journal of the Boston Society of the Medical Sciences* for January 16th, has for its leading article a paper by Theobald Smith on 'Variation among Pathogenic Bacteria,' a subject to which Dr. Smith has paid particular attention for many years. As he states, on the one hand the element of variability has been overlooked, and on the other hand the tendency to concede to bacteria any degree of variability, has given rise to theories which leave but little importance to pathogenic bacteria in the ætiology of disease. The writer concludes that since new disease germs are not constantly appearing the inference is that most species cannot adapt themselves to a parasitic existence. Mark W. Richardson has a note 'On the Cultivation of the Typhoid Bacillus from Rose Spots'; E. W. Taylor describes a case of 'Gumma of the Oblongata,' remarkable for the location and size of the tumor, and James H. Wright notes 'A Simple Method for Anaërobic Cultivation in Fluid Media.'

A Revue des revues d'histoire naturelle has been established at Paris under the direction of MM. Coupin and de Courdirban. It is published bi-monthly.

Dr. A. S. Eakle, assistant in mineralogy at the University Museum, has become the American editor for Groth's *Zeitschrift für Krystallographie.*

SOCIETIES AND ACADEMIES.

NEW YORK ACADEMY OF SCIENCES.

SECTION OF BIOLOGY.

At the meeting of February 12, 1900, presided over by Professor Bashford Dean, the following program was offered:

J. A. MacGregor, 'On the Development of the Skull in Ceratodus.'

F. B. Sumner, 'Kupfer's Vesicle in Relation to Gastrulation and Concrescence.'

G. S. Huntington, 'Some Muscle Variations of the Pectoral Girdle.'

J. H. MacGregor gave a brief preliminary report on the development of the skull in Ceratodus, the Australian lung-fish. The research was made conjointly with Professor Bashford Dean.

Only the early stages of the chondrocranium have as yet been studied; but it is noteworthy that these early stages show even closer resemblance to the amphibian skull than does the adult. The suspensorium is autostylic from the first, and the union of quadrate to cranium by ascending and otic processes is exactly as in urodele amphibia. The hyomandibular appears later than the body of the hyoid arch, and has no connection with the jaws. The trabeculæ are widely separated, leaving a large ventral fontanelle, also an amphibian character. The palatopterygoid bar is almost entirely suppressed. The one character which is entirely fishlike is the otic capsule.

A summary of Mr. Sumner's paper is as follows:

I. The generally accepted account of the gastrulation in the Teleosts as proposed first by Götte, was shown to be incomplete, in so far as it failed to give a true account of the hypoblast.

II. A view of Kupfer's vesicle was maintained, closely similar to that proposed by the great morphologist after whom the structure has been named.

III. The present author has arrived, on purely morphological grounds, at a view of concrescence identical with that proposed by Kopsch on the basis of the latest experimental work.

Dr. George S. Huntington's paper dealt specifically with the retro-clavicular group of supernumerary muscles, for the purpose of determining their mutual relationship and common derivation. The new muscle, here described for the first time, completes a series of retro-clavicular aberrant muscles which represent different stages in migration and recession of the typical mammalian M-sterno-chondro-scapularis. The members of this group appear therefore as myo-typical reversions representing persistent portions of this muscular plane, with secondary skeletal attachments depending upon the degree of recession.

FRANCIS E. LLOYD,
Secretary.

SECTION OF GEOLOGY AND MINERALOGY.

AT the meeting of February 19, 1900, with Mr. G. F. Kunz in the chair, there were sixteen persons present.

Professor R. E. Dodge announced the death of Dr. Hans Bruno Geinitz on December 30, 1899. He also stated that Professor J. J. Stevenson had been appointed by the Council of the Academy as delegate to the coming meeting of the International Geological Congress, and that the Council had voted to become a subscriber to the fund of that Congress.

The Chairman briefly discussed the character and work of Dr. Geinitz, and, on motion, Professor Stevenson was appointed a committee to prepare a minute on this great loss to the Academy and to science.

The following specimens were exhibited by the Chairman:

Corundum from Raglan Township, Ontario, Canada.

Variously colored sapphires from a new locality, Clear Creek, Granite county, Montana.

Corundum from a serpentine dike at a new locality, Corundum Hill, Plumas county, California.

The regular paper of the evening was then read by Dr. Henry S. Washington, illustrated by diagrams and specimens:

'The Igneous Complex of Magnet Cove, Arkansas.' The structure of the complex is described and, from the evidence of the form of the area, the relations to the surrounding shales, the presence of an overlying zone of metamorphosed rock, the arrangement of, and the serial petrographical and chemical characters of the main rock types, with other minor points, the conclusion is drawn that the igneous complex is probably a laccolith, and certainly a unit; and that the main component abyssal rocks are not due to successive injections, as was suggested by J. F. Williams, but are the result of a differentiation *in situ* of the mass of magna.

The main rock types are described, some new analyses being given, and they are shown to form a regularly graded series of interesting rocks, ranging from basic jacupirangite, through biotite-ijolite, typical ijolite, shonkinitic syenite and leucite-syenite, to foyaite. This serial, and common genetic character is shown both mineralogically and chemically. It is probable that the dikes of tinguaite and nepheline-porphyry are aschistic, while those of monchiquitic rocks are diaschistic.

The arrangement of the abyssal rocks is shown to differ radically from most other cases of differentiated laccolithic masses and dikes, in that there is progressive increase in acidity toward the periphery. One or two other instances of this are mentioned, the most closely analogous being the laccolith at Umptek in Kola (Finland).

An explanation of this is given, based on a process of fractional crystallization or freezing of the magma, and the idea applied to other cases. It is suggested that the laccoliths and similar magnetic masses, which have been studied, may be referred to three distinct types, the differences between which would be satisfactorily accounted for by the hypothesis.

In the ensuing discussion Dr. Washington pointed out that the specimens of the rocks represented by his analysis had not been selected in a radial line, but at various directions at increasing distances from the central mass of basic constitution.

Alexis A. Julien,
Secretary of Section.

TORREY BOTANICAL CLUB.

At the meeting of January 31, 1900, six new members were elected.

The scientific program consisted of a paper on the cultivation of palms, by Mr. Henry A. Siebrecht. After a general discussion of the palms as a botanical group, and of the various types represented in tropical regions, a full and interesting account was given of their cultivation in conservatories and as house plants, with valuable suggestions for their treatment and care in the household. The characters of various species suitable for cultivation indoors were given, especially of the genera *Cocos*, *Kentia*, *Phœnix*, *Areca*, *Caryota*, *Licula* and *Thrinax*, of which fine illustrations were shown from Mr. Siebrecht's nurseries. Among these were *Cocos Weddelliana*, *Phœnix Canariensis*, *P. Rupicola*, *Areca lutescens* and *Licuala grandis*. An accoant of Mr. Siebrecht's extensive nurseries in the tropical regions of Trinidad was afterwards added by request of some of the members.

Discussion followed by Mr. Henshaw, Mr. Lighthipe and Dr. Rusby.

L. M. Underwood,
Secretary pro. tem.

PHILOSOPHICAL SOCIETY OF WASHINGTON.

The 513th meeting of the Society was held at the Cosmos Club on February 17th. Professor T. J. J. See, of the Naval Observatory, on behalf of the committee on Mathematical Science, presented a brief report on the progress of Theoretical Astronomy during 1899. Attention was drawn to the completion of *M. Poincaré's Méthodes nouvelle de la mécanique*, a work of the highest theoretical interest, and promising important practical extension in certain directions. It seemed probable that the methods depending on periodic solutions will be of much greater use in connection with the theories of stability and limits of variations, than in the practical construction of tables.

The progress of the Lunar Theory in the hands of Professor E. W. Brown was noted, and attention was drawn to the necessity for a practical test of the theory in the way of the construction of new tables for the Moon. The speaker thought the Nautical Almanac Office might take up the Lunar Theory in the near future as one of its principal lines of work.

The report noted the progress of Professor Eichelberger's researches on the tables of the Watson Asteroids, and Professor Stone's researches on the theory of the perturbation of Hyperion. Attention was also called to Professor Brown's researches on the satellite of Neptune, which enabled him to deduce the oblateness of the planet from its perturbative effect on the motion of the Satellite.

Professor See referred to his own researches on the Sun's heat, recently published by the Academy of Science of St. Louis, and said he had some investigations in progress which would give more accurate theories of the densities and moments of inertia of the planets. In conclusion it was pointed out that if no discovery of an especially striking character had been made during the past year, it was apparent that the progress was steady and continuous, and touched some of the most delicate problems of the heavens.

Mr. Henry Farquhar read a paper on the 'Formation of a table of *n*th powers by means of their successive differences.' A rule was given and demonstrated for calculating any power of the natural series of numbers from 0 upwards, by simple addition, combined with multiplication by factors in no case exceeding the index of the power. The first number in the series of first differences is always 1 ; the first in that of the second differences the difference between $2^n - 1$, and 1 or $2^n - 2$; while the third series is evidently headed by $3^n - 3 \cdot 2^n + 3$, the fourth by $4^n - 4 \cdot 3^n + 6 \cdot 2^n - 4$, and the q^{th} by

$$q^n - q(q-1)^n + \frac{q(q-1)}{2}(q-2)^n - \frac{q(q-1)(q-2)}{2 \cdot 3}(q-3)^n + \cdots$$

The derivation of these numbers for the nth power from similar numbers for the $n-1$th power is very simple, since

$$q^n - q(q-1)^n + \frac{q(q-1)}{2} q-2)^n - \cdots = q\Big[q^{n-1} - q(q-1)^{n-1} \cdot + \frac{q(q-1)}{2}(q-2)^{n-1} - \cdots + (q-1)^{n-1} - (q-1)(q-2)^{n-1} + \cdots\Big]$$

The table below shows the succession of leading differences for each power as far as the fifth ; figures in the column to the left denoting powers, and each number in the body of the table being the sum of that immediately above it and that immediately to the left of the latter, multiplied by the factor at the head of its column. The calculation of a table of fourth powers is also indicated to the right ; the numbers at the top being taken from the preceding table, and each of the rest being the sum of that immediately above it and that immediately to the right of the latter. The number 24, in the last column, is a constant additive to the column preceding. The successive fourth powers appear in the left-hand column of the calculation.

A paper by Mr. J. R. Eastman on the 'Treatment of Reflection Observations at Greenwich Observatory,' announced for the evening, was not read on account of the unavoidable absence of the author.

E. D. PRESTON,
Secretary.

GEOLOGICAL SOCIETY OF WASHINGTON.

THE 98th regular meeting was held at the Cosmos Club, February 28, 1900.

Under informal communications Mr. G. K. Gilbert called attention to the peculiar level character of the ledges of rock crossing the bed of the Potomac, just above Harpers Ferry, and also in the bed of the Columbia river, near the mouth of the Umatilla. It was suggested that subaërial disintegration is effective in reducing, to approximately the water level, those portions of the rocky bed which are not ordinarily covered with water.

On the regular program Mr. W J McGee presented a paper on 'The Gulf of California as an Evidence of Marine Erosion.' It was shown that the powerful tides of the Gulf, aided by frequent gales, are the cause of vigorous marine erosion where the tidal currents are constricted by the islands Tiburon, Esteban, and San Lorenzo. The erosion results in submarine terraces, up to a mile in width, covered with shallow water, and backed by precipitous coastal cliffs. At the outer edges of these terraces there is a rapid descent into deep water.

A discussion on 'The Conditions of Formation of Conglomerates, and Criteria for distinguishing between Lacustrine and Fluviatile Beds,' was introduced by a paper from Professor W. M. Davis, briefly summarizing the criteria available for discriminating the two classes of deposits, and suggesting that the term *continental* proposed by Penck, should be used in those cases where it is not possible to determine whether a given deposit is lacustrine or fluviatile.

Mr. G. K. Gilbert followed with a short analysis of the conditions governing the formation of conglomerates. The dominant agencies are littoral and fluviatile. Hence the presence of conglomerates, in the absence of contrary evidence, indicates stream or shore action. The formations of Lake Bonneville and the superficial deposits of the Great Plains were determined as lacustrine and fluviatile respectively, not from the internal evidence of the deposits, but on physiographic grounds.

Mr. S. F. Emmons, referring especially to the regions covered by the Fortieth Parallel

Survey, stated that a fluviatile origin for the tertiary beds of the west was not considered, because their lacustrine nature was indicated by physiographic evidence.

Mr. Whitman Cross cited Blanford's description, published in 1879, of the Gondwána beds in India, and pointed out that the conclusion, then announced, as to the probable origin of these and other beds in India had probably been overlooked by geologists quite generally. The same criteria applied to the tertiary and mesozoic beds of the Rocky Mountain region would lead to the conclusion that many of them were of fluviatile origin. Mr. Cross, however, questioned the value of the criteria employed by Blanford, Penck and Davis, and would give most weight at present to the extent and distribution of the formations in question, and their relation to continental areas.

Mr. Bailey Willis remarked that he had been in the habit of reasoning back from conglomerates in order to reconstruct former physiographic conditions. Thus the conglomerate of the Puget Sound Basin, covering perhaps 10,000 square miles, was formed by glacial streams in Pleistocene time. The Pliocene conglomerates of California are delta deposits and are associated with uplift. The Eocene conglomerate of Washington State was laid down at the foot of steep bluffs of granite. The Pottsville conglomerate, composed almost wholly of residual quartz and widely distributed, can have been derived only from a coastal plain where it had been concentrated by marine action, and thence distributed by marine or fluviatile currents.

Mr. G. F. Becker pointed out that a lake was often only an expanded river and suggested that a more useful distinction than that between lacustrine and fluviatile deposits, would be one between materials laid down in rapidly moving and in comparatively still water. Deposits laid down by streams have their particles imbricated in one dominant direction. Beach deposits are capriciously imbricated and their pebbles are asymmetric.

F. L. RANSOME,
DAVID WHITE,
Secretaries.

BIOLOGICAL SOCIETY OF WASHINGTON.

THE 319th meeting was held on Saturday evening, February 24th. W. A. Orton spoke of 'The Sap Flow of the Maple in Spring,' describing a series of experiments undertaken with a view of ascertaining the cause of the the phenomenon. The results showed that it was due to plant physics rather than plant physiology, and had a direct relation to temperature, the sap being expelled by the expansion, caused by warmth, of the gas contained in the wood cells. M. B. Waite described 'The Peach Orchards of Michigan,' stating that they were located on the eastern shore of Lake Michigan, this body of water having the effect of mitigating the temperature of the region. Most of the farms, the speaker stated, were comparatively small, running from fifty to eighty acres in size, but owing to the methods of cultivation they yielded a good profit. Various methods of cultivation were discussed and the speaker touched briefly upon the disease of the peach known as 'little peach.' Both papers were illustrated by lantern slides.

F. A. LUCAS.

DISCUSSION AND CORRESPONDENCE.

INFINITESIMALS.

TO THE EDITOR OF SCIENCE: Will you kindly accord me space for a few remarks about Infinity and Continuity which I seem called upon to make by several notes to Professor Royce's Supplementary Essay in his strong work 'The World and the Individual'? I must confess that I am hardly prepared to discuss the subject as I ought to be, since I have never had an opportunity sufficiently to examine the two small books by Dedekind, nor two memoirs by Cantor, that have appeared since those contained in the second volume of the *Acta Mathematica.* I cannot even refer to Schröder's Logic.

1. There has been some question whether Dedekind's definition of an infinite collection or that which results from negativing my definition of a finite collection is the best. It seems to me that two definitions of the same conception, not subject to any conditions, as a figure in space, for example, is subject to geometrical conditions, must be substantially the

same. I pointed out (*Am. Journ. Math.* IV. 86, but whether I first made the suggestion or not I do not know) that a finite collection differs from an infinite collection in nothing else than that the syllogism of transposed quality is applicable to it (and by the consequences of this logical property). For that reason, the character of being finite seemed to me a positive extra determination which an infinite collection does not possess. Dr. Dedekind defines an infinite collection as one of which every *echter Theil* is similar to the whole collection. It obviously would not do to say a *part*, simply, for every collection, even if it be infinite, is composed of individuals; and these individuals are parts of it, differing from the whole in being indivisible. Now I do not believe that it is possible to define an *echter Theil* without substantially coming to my definition. But, however that may be, Dedekind's definition is not of the kind of which I was in search. I sought to define a finite collection in logical terms. But a 'part,' in its mathematical, or collective, sense, is not a logical term, and itself requires definition.

2. Professor Royce remarks that my opinion that differentials may quite logically be considered as true infinitesimals, if we like, is shared by no mathematician '*outside of Italy*.' As a logician, I am more comforted by corroboration in the clear mental atmosphere of Italy than I could be by any seconding from a tobacco-clouded and bemused land (if any such there be) where no philosophical eccentricity misses its champion, but where sane logic has not found favor. Meantime, I beg leave briefly to submit certain reasons for my opinion.

In the first place, I proved in January, 1897, in an article in the *Monist* (VII. 215), that the multitude of possible collections of members of any given collection whatever is greater than the multitude of the latter collection itself. That demonstration is so simple, that, with your permission, I will here repeat it. If there be any collection as great as the multitude of possible collections of its members, let the members of one such collection be called the A's. Then, by Cantor's definition of the relation of multitude, there must be some possible relation, r, such that every possible collection of A's is r to some A, while no two possible collections of A's are r to the same A. But now I will define a certain possible collection of A's, which I will call the collection of B's, as follows: Whatever A there may be that is not included in any collection of A's that is r to it, shall be included in the collection of B's, and whatever A there may be that is included in a collection of A's that is r to it, shall not be included in the collection of B's. If there is any A to which no collection of A's stands in the relation r, I do not care whether it is included among the B's or not. Now I say the collection of B's is not in the relation r to any A. For every A is either an A to which no collection of A's stands in the relation r, or it is included in a collection of A's that is r to it, or it is excluded from every collection of A's that is r to it. Now the collection of B's, being a collection of A's, is not r to any A to which no collection of A's is r; and it is not r to any A that is included in a collection of A's that is r to it, since only one collection of A's is r to the same A, so that were that the case the A in question would be a B, contrary to the definition which makes the collection of B's exclude every A included in a collection that is r to it; and finally, the collection of B's is not r to any A not included in any collection of A's that is r to it, since by definition every such A is a B, so that, if the collection of B's were r to that A, that A would be included in a collection of A's that was r to it. It is thus absurd to say that the collection of B's is r to any A; and thus there is always a possible collection of A's not r to any A; in other words, the multitude of possible collections of A's is greater than the multitude of the A's themselves. That is, every multitude is less than a multitude; or, there is no maximum multitude.

In the second place I postulate that it is an admissible hypothesis that there may be a something, which we will call a *line*, having the following properties: 1st, points may be determined in a certain relation to it, which relation we will designate as that of 'lying on' that line; 2d, four different points being so determined, each of them is separated from one of the others by the remaining two; 3d, any three points, A, B, C, being taken on the line, any multitude whatever of points can be determined upon it so that every one of them is separated from A by B and C.

In the third place, the possible points so determinable on that line cannot be distinguished from one another by being put into one-to-one correspondence with any system of 'assignable quantities.' For such assignable quantities form a collection whose multitude is exceeded by that of another collection, namely, the collection of all possible collections of those 'assignable quantities.' But points are, by our postulate, determinable on the line in excess of that or of any other multitude. Now, those who say that two different points on a line must be at a finite distance from one another, virtually assert that the points are distinguishable by corresponding (in a one-to-one correspondence) to different individuals of a system of 'assignable quantities.' This system is a collection of individual quantities of very moderate multitude, being no more than the multitude of all possible collections of integral numbers. For by those 'assignable quantities' are meant those toward which the values of fractions can indefinitely approximate. According to my postulate, which involves no contradiction, a line may be so conceived that its points are not so distinguishable and consequently can be at infinitesimal distances.

Since, according to this conception, any multitude of points whatever are determinable on the line (not, of course, by us, but of their own nature), and since there is no maximum multitude, it follows that the points cannot be regarded as constituent parts of the line, existing on it by virtue of the line's existence. For if they were so, they would form a collection; and there would be a multitude greater than that of the points determinable on a line. We must, therefore, conceive that there are only so many points on the line as have been marked, or otherwise determined, upon it. Those do form a collection; but ever a greater collection remains determinable upon the line. *All* the determinable points cannot form a collection, since, by the postulate, if they did, the multitude of that collection would not be less than another multitude. The explanation of their not forming a collection is that all the determinable points are not individuals, distinct, each from all the rest. For individuals can only be distinct from one another in three ways: First, by acts of reaction, immediate or mediate, upon one another; second, by having *per se* different qualities; and third, by being in one-to-one correspondence to individuals that are distinct from one another in one of the first two ways. Now the points on a line not yet actually determined are mere potentialities, and, as such, cannot react upon one another actually; and, *per se*, they are all exactly alike; and they cannot be in one-to-one correspondence to any collection, since the multitude of that collection would require to be a maximum multitude. Consequently, all the possible points are not distinct from one another; although any possible multitude of points, once determined, become so distinct by the act of determination. It may be asked, "If the totality of the points determinable on a line does not constitute a collection, what shall we call it?" The answer is plain: the possibility of determining more than any given multitude of points, or, in other words, the fact that there is room for any multitude at every part of the line, makes it *continuous*. Every point actually marked upon it breaks its continuity, in one sense.

Not only is this view admissible without any violation of logic, but I find—though I cannot ask the space to explain this here—that it forms a basis for the differential calculus preferable, perhaps, at any rate, quite as clear, as the doctrine of limits. But this is not all. The subject of topical geometry has remained in a backward state because, as I apprehend, nobody has found a way of reasoning about it with demonstrative rigor. But the above conception of a line leads to a definition of continuity very similar to that of Kant. Although Kant confuses continuity with infinite divisibility, yet it is noticeable that he always defines a continuum as that of which every part (not every *echter Theil*) has itself parts. This is a very different thing from infinite divisibility, since it implies that the continuum is not composed of points, as, for example, the system of rational fractions, though infinitely divisible, is composed of the individual fractions. If we define a continuum as that every part of which can be divided into any multitude of parts whatsoever —or if we replace this by an equivalent definition in purely logical terms—we find it lends itself at once to mathematical demonstrations, and enables us to work with ease in topical geometry.

3. Professor Royce wants to know how I could, in a passage which he cites, attribute to Cantor the above opinion about infinitesimals. My intention in that passage was simply to acknowledge myself, in a general way, to be no more than a follower of Cantor in regard to infinity, not to make him responsible for any particular opinion of my own. However, Cantor proposed, if I remember rightly, so far to modify the kinetical theory of gases as to make the multitude of ordinary atoms equal to that of the integral numbers, and that of the atoms of ether equal to the multitude of possible collections of such numbers. Now, since it is essential to that theory that encounters shall take place, and that promiscuously, it would seem to follow that each atom has, in the random distribution, certain next neighbors, so that if there are an infinite multitude in a finite space, the infinitesimals must be actual real distances, and not the mere mathematical conceptions, like $\sqrt{-1}$, which is all that I contend for.

C. S. PEIRCE.

MILFORD, PA., Feb. 18, 1900.

CURRENT NOTES ON PHYSIOGRAPHY.

DEFLECTION OF RIVERS BY SAND-REEFS.

AN article on 'The effect of sea barriers upon ultimate drainage' by J. F. Newsom (*Journ. Geol.*, vii, 445–451), describes several examples of rivers whose discharge is deflected to the right or left by the formation of an offshore sand-reef in front of their mouths, and suggests that such deflection may explain the course of rivers that now flow parallel to preexistent coast lines; for example, the Delaware below Bordentown, N. J.

This suggestion is evidently valid as a possibility, but it is not accompanied by tests that sufficiently distinguish deflections thus caused from deflections that arise from the spontaneous adjustment of streams to the weak strata that underlie the cuesta-makers of coastal plains having longitudinal relief. The lower Delaware cannot be a normal example of the latter class, because as the master river of its region it is the very one that should not be deflected by adjustment; on the other hand, it may truly fall under the former class because its deflection is in the sense of the dominant sand-drift along our Atlantic Coast. Examples of sand-reef deflections ought to follow the strike of strong or weak rocks, indifferently; while normal deflections by adjustment can only follow belts of weak rocks.

DEVELOPMENT OF THE SEVERN.

THE systematic development of rivers seldom finds better illustration than in the interaction of the 'waxing Severn and the waning Thames,' concerning which a number of new details and suggestions are given by S. S. Buckman (*Nat. Science*, xiv, 1899, 273–289). The growth of the Severn by headward erosion along the weaker strata that underlie the firmer oölites of the Cotteswold hills is advocated on good evidence, and a restoration of the original consequent headwaters that have now been diverted from the Thames system is attempted. The growth of obsequent branches of the subsequent Severn on the line of the beheaded consequent branches of the Thames is well presented as the reason for the peculiar unsymmetrical arrangement of the Severn tributaries in the neighborhood of Gloucester. The Frome, a branch of the Severn, is shown to have captured several of the westernmost headwaters of the Thames in the Cotteswold hills between Chalford and Edgeworth. The progressive diminution of the Coln, a branch of the Thames, by the successive diversion to the Severn of the two large branches that once came from Wales is offered in explanation of the very curious features of the present Coln valley in the upland east of Cheltenham: a valley of large-curve meanders is taken as the work of the original river; a narrower valley of small meanders, cut in the floor of the larger valley, is the work of the river after one of its upper branches was captured by the Severn; the wriggling course of the present stream on the floor of these smaller meanders is due to the further loss of volume after the second upper branch was captured.

Some further account of the Cotteswold streams and of their homologues in the Swabian Alp of southern Germany may be found in a paper by the undersigned on the 'Drainage of Cuestas' (Proc. Geol. Assoc., London, xvi, 1899, 75–93). The failure of even the obsequent streams fully to occupy their meandering valleys suggests that all the streams of the region have diminished in volume on account of climatic change or of deforesting and cultivation; beheading is therefore not alone the cause of the misfit of the Coln and its neighbors in the upper Thames system.

LANDQUART AND LANDWASSER.

Heim's explanation of the diversion of the upper waters that once belonged to the Landwasser by the headward growth of the Landquart in the Alps of eastern Switzerland has been made familiar in Lubbock's 'Scenery of Switzerland.' A serious difficulty that stands in the way of this explanation is presented by A. V. Jennings (*Geol. Mag.*, London, 1899, 259–270); namely, that the growth of the Landquart before its capture of the upper Landwasser would have had to be through a belt of resistant rocks, which usually rise high in ridges and peaks. If the capture really took place, it seems to have been long ago, for the divide at the head of the Landwasser appears to be formed not of bed rock as Heim implies, but of heavy morainic deposits by which certain streams, once captured by the Landquart, are now returned to the Landwasser.

Certain lines of evidence that might be found in connection with the form and attitude of the valley floors before the time of capture are not mentioned.

RIVER GORGES OPPOSITE LATERAL FANS.

A journey in Bokhara by Rickmers (*Geogr. Journ.*, xiv, 1899, 596–620) led to the headwaters of the Oxus, where a great body of conglomerates is deeply dissected, producing bad lands on a gigantic scale well illustrated by figures from photographs. The relation of the conglomerates to the lofty snow mountains further east suggests that the former represent an ancient 'wash' from the latter, the whole region now being uplifted and trenched. The local stream in a branch valley of the Yakh river excited the curiosity of the traveller by alternately passing through open basins and narrow rock-walled gorges, and as Rickmers was 'unable to find any mention of a similar phenomenon in the literature on the subject,' especial description of these 'Dandushka barriers' is given. They appear to be examples of gorges produced by a stream that has been displaced from the axis of its valley by the growth of large lateral fans such as may be seen in the upper Engadine of Switzerland. They are, therefore, analogous to gorges due to local displacement and superposition of streams on rocky beds by the irregular distribution of glacial drift, but they are of peculiar interest from their spontaneous production by the interaction of different members of a single drainage system. Although such features of a valley are as well specialized as the thorns and galls of a twig, they are not likely to be given any conveniently designative name by British geographers, inasmuch as one of the honorary secretaries of the Royal Geographical Society recently takes occasion to say that "the invention of a new scientific word is always a positive evil, to be avoided if possible" (*Geogr. Journ.*, 1899, 658). On the supposition that nothing worth naming remains to be discovered in scientific geography, this dictum may have value; but a hundred years hence geographers will probably look on the geographical terminology of to-day as we do on that of our predecessors a hundred years ago, when atoll and caldera, mesa and canyon, moraine, drumlin, esker and kame had no place in the English language.

AN AVALANCHE TRACK ON MT. SHASTA.

Among many items of interest in the introductory pages of Merriam's 'Biological Survey of Mount Shasta' (U. S. Dept. Agric., *N. Amer. Fauna*, No. 16, 1899), is the account of the path formed by a recent avalanche that must have been of unusual size, through a forest of large firs. After gaining headway in descending from the upper slopes, the snow cut a broad swath through the huge trees, carrying their trunks forward over a gently sloping tract, and strewing hundreds of great logs 75 to 100 feet long and 3 or 4 feet in diameter, in confusion over the broad area where the slide finally came to rest. Here a few trees that were left standing are deeply scarred 10 or 15 feet above the ground where they were struck by trunks that were carried forward over deep snow. A number of excellent heliotype views are given of the mountain, the frontispiece being particularly fine.

ZOOLOGICAL NOTES.

REGENERATION AND LIABILITY TO INJURY.

IN a recent number of the *Anatomischer Anzeiger*, Professor T. H. Morgan gives an account of his later experiments on the regeneration of the appendages of the hermit-crab. It will be remembered that his first experiments, made at Woods Hole in 1898, showed that certain appendages, because of their protection within the mollusk shell in which the crab lives, regenerate after artificial amputation quite as readily as the more exposed appendages which in nature are constantly liable to injury, and which actually reveal a much higher percentage of injuries. This result was clearly at variance with the opinion of those who believe that there is a definite relation between the regenerative capacity of a part and its liability to injury.

Professor Weismann attempted to explain the phenomenon by attributing to the more or less protected appendages of the hermit-crab the inherited regenerative power of some remote ancestor—an ancestor which was not domiciled in a shell. Moreover, he thought the fact that the power of autotomy was possessed by the three anterior thoracic appendages—parts frequently subject to injury—and not possessed by the two protected posterior pairs, was evidence of the comparatively recent origin of autotomy, and the more remote origin of regeneration, Morgan having shown that the fourth and fifth pairs of legs do regenerate. In stating that "The adaptation for autotomy once gained, the power of regeneration had of necessity to become localized; that is to say, the apparatus necessary for it had to be transferred to those parts at which alone the breaking off of the the limb occurs," Professor Weismann gave, to use his form of expression, a new lead which Morgan has again followed in his series of experiments of the summer of 1899. These experiments show that the power of regeneration has *not* become localized, and that the first three thoracic legs can regenerate both when cut off proximal to, and when cut off distal to the breaking-point of autotomy. Moreover, the experiments of Morgan incidentally give additional reasons for his earlier conclusion that there is no relation between regeneration and liability to injury, for in removing the appendages, at a point proximal to the 'breaking-joint,' he laid bare a regenerative zone, which in a state of nature must almost never be called upon to exercise the function of repair.

Weismann's suggestion that in the last abdominal appendage the regenerated part would be renewed after the pattern of a tail-fin of the Macroura, rather than after the original pattern of a 'holdfast,' is shown not to be supported by the facts.

H. C. B.

COMFORT AND PRODUCTIVITY.

M. MAX GERARD, in the *Bulletin Scientifique*, of the University of Liege, January, 1900, shows the influence of the compensation of the workman upon the productivity of establishments, taking his data from Dechesne, Ansiaux, and Waxweiler. He places the values of services and products, as reported from the several countries, in certain cases, thus:

	Wages per diem.	Value of product: Labor per tonne.
United States	12.20 fr.	17.15 fr.
Great Britain	6.25 "	15.15 "
France	4.15 "	16.90 "
Belgium	3.20 "	10.50 "

It is thus found that the cost of the product is, as a rule, very slightly affected, in these different countries by the wages paid their workmen, and France, paying one third the wage given in the United States, finds the product to cost practically the same amount. Great Britain, paying one-half the wages paid in the United States, produces very little more cheaply. Belgium pays little more than one-fourth the wages ruling in similar establishments in America and the product costs two-thirds as much, and even this difference may be due, in some degree, to other conditions.

The author of the paper accounts for these facts by the interaction of wages and morale, largely, partly by the better nutrition of the well-paid man and his improved strength and spirits and ambition. He states that the engineers building the railway from Paris to Rouen made the experiment of furnishing the same nourishing and plentiful diet to their French laborer as was demanded by and habitually supplied to the Englishman working beside him, with the result that, after a short time, the product of the two men became the same. The four cases above were selected from among establishments doing substantially the same sort of work and marketing practically the same quality of product.

"On ne peut expliquer ces faits que par la productivité élevée de l'ouvrier américain qui possède plus d'activité, plus de vigilance, plus d'application au travail que ses concurrents. Il est effectivement placé dans des conditions supérieure au point de vue matériel, intellectuel et moral."

Rankine, in his 'Prime Movers,' makes substantially the same enunciation of a principle, recognized by every experienced manager of works, when, referring to the physical working effect of men and beasts, he states that the daily product depends upon the "health, strength, activity and disposition of the individual," and on the "abundance and quality of food and air, the climate, and other external conditions."

R. H. Thurston.

SCIENTIFIC NOTES AND NEWS.

Mr. Dean C. Worcester, assistant professor of zoology and curator of the Zoological Museum at the University of Michigan, has been appointed a member of the new Philippine Commission. Professor Bernhard Moses, of the chair of political economy of the University of California, has also been appointed a member of the Commission.

The Paris Academy of Sciences has elected as foreign correspondents, Dr. C. Zittel, professor of paleontology in the University of Munich, and Professor Wilhelm Pfeffer, professor of botany at the University at Leipzig.

Dr. A. Smith Woodward, of the Department of Geology of the British Museum, will visit the United States in the spring to study the cretaceous vertebrates in American museums.

Mr. J. B. Woodworth, instructor in geology at Harvard University, has been appointed assistant on the New York Geological Survey to study glacial features of New York. Mr. Woodworth will begin his studies in the lower Hudson Valley in the season of 1900.

Professor O. C. Farrington, of the Field Columbian Museum, has been appointed on the staff of the Commissioner General of the United States to the Paris Exposition, and will spend two months in Paris supervising the installation of the United States mineralogical exhibit.

Dr. Edward Ehlers, of Copenhagen, will go next month to Crete to make arrangements for the segregation of the lepers on the island. There are about 2000 of these and they will be placed on a small island off the north coast.

It is announced in *Nature* that Dr. C. L. Griesbach, the director of the Geological Survey of India, has gone for a tour in the famine districts of the Central Provinces, Bombay and Rajputana, with a view to examining into the practicability of sinking artesian wells.

The Faculty of Medicine, of Würzburg, has awarded its Rinecke Prize of 1000 Marks and a silver medal to Professor J. v. Kries, for his researches in physiology.

The adjudicators of the Hopkins prize, University of Cambridge, for the period of 1891–94, have awarded the prize to W. D. Niven, M.A., F.R.S., formerly Fellow of Trinity, for his memoir on 'Ellipsoidal Harmonics' (*Philosophical Transactions*, 1891) and other valuable contributions to applied mathematics.

We regret to record the death of Dr. Oliver Payson Hubbard, in New York City, on March 9th. He was born in Pomfret, Conn., in 1809 and graduated from Yale University in 1828. He acted as assistant to the elder Silliman whose daughter he married. He was appointed professor in Dartmouth College in 1836, having charge of chemistry and geology, and has since 1883 been emeritus professor. Dr. Hubbard was one of the founders of the American Association for the Advancement of Science.

Professor F. L. Harvey, who held the

chair of natural history in the University of Maine, committed suicide on March 6th. Mental depression resulting from overwork is assigned as the cause. He was born in 1850, graduated from the Iowa Agricultural College in 1868 and was appointed professor in the University of Maine in 1886. He was also botanist and entomologist to the Maine Experiment Station.

The death is announced of Senator Beltrami, professor of mathematical physics in the University of Rome and president of the Accademia dei Lincei.

Herr Daimler, the inventor of the motor car bearing his name, has died at the age of 66 years. His gasoline motor may be regarded as the starting point of the automobile.

Professor E. B. Fernow of Cornell University, lectured at Lehigh University on March 9th, his subject being 'The Evolution of the Forest.'

Mr. H. F. Newell, hydrographer of the United States Geological Survey, delivered an address before the Engineering Society of Harvard University, on March 7th, on the investigations being made by the division of hydrography.

A bronze medallion with a relief portrait of Pasteur has been placed on the house in Strassburg in which he lived in 1852.

Mr. Charles Whitehead, who has acted as technical adviser to the British Agricultural Department of the Privy Council, and subsequently to the Board of Agriculture, during the past fifteen years, has been compelled to resign that appointment owing to ill health.

Dr. Fridtjof Nansen expects to leave Christiania on May 15th in a specially constructed vessel to carry out hydrological investigations around Iceland for the Norwegian Government. The expedition will return in the autumn.

The case of Professor Neisser, of Breslau, accused of making vaccination experiments on human subjects, was again brought up in the Prussian Diet last week. It was reported for the Minister of Education, that the question had been taken up by the state attorney, but that prosecution was barred by the statute of limitation. Disciplinary proceedings were, however, in progress.

We have already noted that Mrs. Caroline Brewer Croft bequeathed $100,000 for researches into the cause and cure of cancer. This bequest was originally made to Drs. H. K. Oliver and J. C. Warren. They have turned over the bequest to Harvard University, and the medical school has organized the work to be prosecuted. Dr. E. H. Nichols, '86, goes to Europe to study cancer abroad.

In 1891 Mr. J. W. Charles de Soysa offered a bacteriological institute for Ceylon, but his gift was at the time declined. The offer was, however, repeated in 1897 and then accepted. The Institute, which is very well equipped, was opened by the Governor on January 31st. Dr. Marcus Fernando has been appointed the first director.

The Brooklyn Institute of Arts and Sciences has been granted an appropriation of $300,000 for the erection of a new wing for the Museum.

The estimates for the British Museum have been reduced £1000 for the coming financial year, but the trustees have petitioned Parliament to reconsider this decision.

A collection of Irish antiquities, formed during the last seventy years by Mr. T. R. Murray, of Edenderry, has been acquired for Cambridge University by Professor Ridgeway.

The Ithaca *Daily News*, for March, 6th devotes a number of columns to the publication of letters from leading naturalists and educators, advocating the establishment by the New York Legislature of a State Biological Station.

Mr. R. Horton-Smith, Q.C., M.A., of St. John's College, Cambridge, has offered to the University a fund of about £600 for the establishment of a prize for medicine and pathology, in memory of his son Raymond Horton-Smith, M.B., who, after a distinguished career in the university and at St. Thomas' Hospital, died in October, 1899, in his 27th year. The prize is to be awarded annually for the best thesis for the M. D. degree offered by candidates who have taken honors in one of the Triposes. The prize thesis is to be printed, and copies are to be sent to various officers and libraries of the university and the Royal College of Physicians.

The late Professor D. E. Hughes bequeathed £400 to the Paris Academy of Sciences for the establishment of a prize for the most important discovery in physical science, preference being given to a discovery in electricity or magnetism.

Under the direction of Professor A. A. Wright of Oberlin College, systematic excavation has been commenced in Brownhelm, Ohio, near Lake Erie and about twelve miles from Oberlin, to recover mastodon remains, the first of which were discovered several years ago. The jaws and head, both tusks, together with a number of ribs and vertebræ have been obtained in a good state of preservation. The bones are much scattered and lie upon a clay hardpan at the bottom of a muck bed four feet deep.

The Royal Meteorological Society, London, will celebrate its 50th anniversary on April 3d. The Council has arranged for a commemoration meeting to be held at 3 p. m. at the Institution of Civil Engineers, at which the president will deliver an address, and delegates from other societies will be received. In the evening a *conversazione* will be held at the Royal Institute of Painters in Water Colors. On the following day, April 4th, the Fellows will visit the Royal Observatory, Greenwich, and in the evening will dine together at the Westminster Palace Hotel. In view of this jubilee celebration, Mr. G. J. Symons, F.R.S., was elected president at the annual meeting of the Society on January 17th, but owing to illness he has since been obliged to resign this office. Under these circumstances the Council at their last meeting appointed Dr. C. Theodore Williams as the president of the Society.

The Committee of the Liverpool School of Tropical Diseases has decided to send out next month, under the direction of Dr. Annett, another expedition to West Africa. The expedition will make its headquarters in Old Calabar and carry on researches in southern Nigeria. If time and opportunity permit the upper Niger will be visited.

At a meeting of the British Astronomical Association on February 28th, Mr. Maunder announced that sufficient names had not been handed in to justify chartering a steamship to visit the Mediterranean at the time of the solar eclipse in May. A large number of names had been withdrawn owing to the war.

The United States Civil Service Commission announces that in view of the needs of the service all persons who have been examined within the past six months and have failed to attain eligible averages in the following named examinations will be permitted re-examination this spring upon filing new applications. These examinations will be held at various places throughout the country, beginning April 17, 1800: Acting Assistant Surgeon Marine Hospital Service, Aid Coast and Geodetic Survey, Assistant Department of Agriculture, Assistant Examiner Patent Office, Assistant Topographer, Civil and Electrical Engineer, Copyist Ship Draftsman, Farmer, Fish Culturist, Hospital Steward, Industrial Teacher, Meat Inspector, Kindergarden Teacher, Manual Training Teacher, Matron, Mechanical and Electrical Engineer, Physician, Register and Receivers Clerk, Seamstress, Superintendent of Construction, Surveyor General's Clerk General Land Office Service, Teacher, Topographic Draftsman, Trained Nurse.

An International Congress of Medical 'Electrology and Radiology' will be held at Paris from the 22d of July to the first of August. Professor Weiss of the University of Paris, is president and the general secretary is Professor Doner, University of Lille.

The Italian Government has decided to establish a bacteriological laboratory for the study of bubonic plague in the island of Pianosa.

We learn from the *British Medical Journal* that M. Fleury-Ravarin, Member of the Chamber of Deputies for the Rhône Department, has brought in a bill providing for the creation of a national antituberculous institute. The proposed institute is to be devoted to the study of the treatment of tuberculosis and experimental researches on the means to be employed for that purpose. The Société Lyonnaise des Tuberculeux Indigents has undertaken to build the institute at its own cost, and proposes to make it an annex of the free sanatorium which it is about to open at Hauteville, in the mountains of the Bugey district. M. Fleury-Ravarin asks the State to associate itself with this philanthropic work by conferring on the institute the title of 'National,' and granting it an annual subvention of £600.

A MEETING of the Organizing Council of the British Congress of Tuberculosis was held at house of the Royal Medical and Chirurgical Society on February 22d.

THE plague has appeared in Sydney, New South Wales, and on the Island of Cozumel, off the coast of Yucatan. A case has occurred in San Francisco. Deaths are still reported from Honolulu. There is no abatement in India, the deaths at Calcutta being 411 for the last week of which news is at hand.

RECENT issues of the *British Medical Journal* and *Nature* recommend the appointment of Professor William Osler, of Johns Hopkins University, to the chair of the practice of physic, vacant by the death of Sir Thomas Grainger Stewart. *Nature* says:

The desire has been widely expressed in University circles in Edinburgh that the Curators of Patronage, with whom the appointment to the chair of medicine rests, should offer the post to Professor Osler, of the Johns Hopkins University, who is well known as a teacher and clinicist of the highest scientific eminence, and whose acceptance of it would greatly strengthen both the systematic and clinical teaching in the University. It would appear, however, that the Curators have no choice in the matter, but are bound to advertise every vacancy, so that the far more satisfactory and dignified method of appointment by invitation is necessarily excluded. Nevertheless, it is confidently hoped that Professor Osler may be induced to send in a formal application for the chair, since it is certain that his claims would receive every consideration from the present Board of Curators, who have more than once, on recent occasions, shown that they are superior to merely local considerations, and that they have regard in making these appointments solely to the best interests of the University. Professor Osler is a Canadian by birth, and although he has for many years successively occupied the important chairs of medicine in Philadelphia and Baltimore, he has, we believe, never renounced his British nationality. His appointment to Edinburgh, although it would be felt as a serious loss by our kinsfolk on the other side of the Atlantic, would doubtless be considered by them, and especially by our Canadian fellow-subjects, as a graceful recognition that we are one people bound together in science, as in politics, by common interests, and that we are prepared to welcome the best man from whichever side of the water he may hail. Applications for the post, with testimonials, must be lodged with Mr. R. Herbert Johnston, Secretary to the Curators, at 66 Frederick Street, Edinburgh, on or before April 14th."

IN his annual report President Eliot writes of the observatory: "The director reports that the Harvard Observatory, which in 1892 had the second largest income among the great observatories of the world, in 1898, had only the fifth largest, the observatories at Washington, Paris, Greenwich and Pulkowa surpassing it in income and expenditure. This fall is occasioned by the decline in the rate of interest on the funds of the observatory. The observatory is now so well organized and so active and efficient that it will be a great pity if its resources, and, therefore, its powers of usefulness, are permitted to decline. It is the only observatory which maintains a station in the northern hemisphere and in the southern; and its collection of photographs of the entire sky gives it unique means of studying the recent history of the stellar universe. The photographic plates are now kept in a fireproof building; but the library of the observatory, which has become very valuable, is in a wooden building and is, therefore, exposed to complete destruction by fire. A fireproof building, which need not cost more than $15,000 or $20,000, ought to be provided for the safe keeping of this collection." Four volumes of the *Annals* have been in process of publication during the larger part of the year, and more than 30 volumes of the *Annals* have been published during the last 20 years—a rate of publication that is truly astonishing. "On November 28, 1898, Mrs. Williamina Paton Fleming was appointed Curator of Astronomical Photographs, and in that capacity her name appeared in the university catalogue for 1898–99. It is believed that Mrs. Fleming is the first woman who has held an official position in Harvard University. She is well known to astronomers as the discoverer of a remarkable number of new variable stars."

MR. SIMON W. HANAUER, Vice-Consul of the United States at Frankfurt, writes to the Department of State that nothing has been said of the San José scale for months in German papers. It has not yet made its début in a live condition in Germany, thus confirming the opinion of experts that the climatic conditions of Germany are not suited to its perpetuation; but, while the false alarm concerning the introduction and ravages of the San José scale has vanished, its ill effects in the nature of administrative measures against the import of American fruit have continued, and the hardship of these proscriptive ordinances are making themselves so acutely felt that German trade circles and consumers are beginning to protest. The chamber of commerce of the city of Hamburg (one of the most important trade bodies of Germany), in its lately published annual report, says on this subject: "The station which last year was opened in this city for the purpose of investigating the presence of the San José scale on American fruit has a laboratory where two scientifically trained experts, with fourteen assistants, have steadily pursued these investigations in the most circumspect manner. While there may not be any objection to examining 'raw fruit,' the continuation of investigations in regard to 'dried fruits' must be considered an utterly unnecessary hindrance to trade. The sanitary experts, whom the imperial German department of health, as well as the Belgian Government, sent last year to California, have fully confirmed the statements made by German fruit importers that the drying methods in use in the United States effectually kill the insects. Therefore, the scales found on dried fruit from America were dead. The trade suffers great damage from the examination, stricter here than elsewhere, and this chamber of commerce regrets that this unnecessary annoyance and harmful practice was not at once discontinued when the facts became known."

UNIVERSITY AND EDUCATIONAL NEWS.

New York University has received a gift of $100,000—it is reported from Miss Helen Gould—for the erection of a 'Hall of Fame for Great Americans.' Colonades overlooking the Harlem river will be erected containing 150 panels on which will be engraved inscriptions commemorating eminent Americans.

Columbia University has received from Mrs. Robert Goelet the gift of a bronze statue to cost about $25,000. It will represent 'Alma Mater' and will be erected in the court before the library.

Oberlin College has received a gift of $50,000 from Dr. and Mrs. Lucien C. Warner, of New York, for a men's gymnasium.

A bequest of £20,000 has been made to the New College, Hampstead (now a constituent college of London University), under the will of the late Mr. Henry Vaughan.

A daughter of the late Professor Hughes Bennet, of the University of Edinburgh, has offered the University a sum of money to establish an addition to the physiological laboratory for the purposes of research.

The Chicago College of Physicians and Surgeons was three years ago affiliated with the University of Illinois. An agreement has now been made effecting a more complete consolidation which is to last 25 years, and allowing the University of Illinois to secure complete control of the College.

Dr. Harris Hancock, A.B. (Virginia and Johns Hopkins) and Ph.D. (Berlin), has been elected professor of mathematics at the University of Cincinnati to fill one of the chairs recently declared vacant by the Board of Directors. Dr. Hancock has published papers on the Abelian functions, on the calculus of variation and other subjects. He is at present at Paris.

At Oberlin College, Simon F. MacLennan has been appointed professor of psychology and pedagogy, and Frederick O. Grover, professor of botany.

Professor R. S. Lawrence, of Emporia College, Kans., has accepted the chair of mathematics in Hanover (Ind.) College.

Professor Julius Hann, of Gratz, has been called to the professorship of cosmical physics, at Vienna. Dr. August Gutzmer has been made full professor of mathematics in the University of Jena. Dr. v. Schmidt, of Dorpat, has qualified as docent in histology and embryology in the University at Jena.

Dr. Th. M. Fries, professor of botany in the University of Upsala, has retired.

THIRD ANNUAL PURE FOOD AND DRUG CONGRESS.

IN harmony with a call issued by the Executive Committee, the third annual Pure Food and Drug Congress of the United States, assembled in Washington, D. C., on March 7th.

Delegates to this Congress were appointed by the Governors of the several States; by the State boards of agriculture and health; by the agricultural colleges and experiment stations; by the national trade organizations, both by wholesalers and retailers; by the National Grange; by the State Granges and by various other organized bodies. Over five hundred delegates were appointed and about three hundred attended the meeting, thirty-five States and Territories being represented by delegates in actual attendance. The meeting was a thoroughly representative one in every particular.

The principal object of this Congress was to promote national legislation relating to the inter-state traffic in adulterated foods, to provide inspection of food products shipped abroad and to regulate the sale of food products in the Territories of the United States and the District of Columbia. Under the constitution the power of the Congress cannot go farther than this.

For many years agitation in regard to this legislation has been going on, and the fundamental principles of the measure agreed upon have been endorsed by the various interests represented in this and the previous Congresses. The necessity for such legislation is apparent to every one. State laws are effective only when supplemented by national legislation. As long as adulterated foods are permitted to enter one State from another it is not possible for the State authorities to reach the real offender. The State courts can only punish the citizens of their own State, whereas the real culprit may reside across the State border in another jurisdiction. One of the best provisions of this measure, which has been endorsed by this Pure Food Congress, is that the original manufacturer or producer of the goods can be punished, while the innocent retailer or dealer may escape, by tracing the articles to their original source, and thus furnish evidence to convict the primary offender.

Another excellent provision of the proposed law, as endorsed by the Congress, is the inspection of food products intended for export to foreign countries. It is well known that many of our food products have been unjustly condemned in foreign countries, on alleged sanitary grounds or on alleged imperfections. Inasmuch as these food products have received no inspection before leaving the country it is quite difficult for our citizens to establish the character and purity of their exported food products. With rigid inspection by Government officials, before export, it would be a comparatively easy matter to maintain the rights of our food products in foreign countries. By reason of the increased scope and magnitude of the work of the Division of Chemistry and in harmony with the recommendations contained in the last annual report of the Secretary of Agriculture, to the President of the United States, the proposed legislation endorsed by the Pure Food Congress raises the Division of Chemistry to the dignity of a bureau.

Another excellent feature of the proposed measure is the absence of annoying, restrictive or prohibitive clauses. The pure food bill, as recommended by the Congress, does not inflict upon any honest dealer any rules or regulations, which will interfere in any way with his trade or make it difficult for him to conduct his business.

If the question of wholesomeness arises a provision is made for its study in a thoroughly impartial and effective manner. The bill provides for a board to be appointed by the President of the United States and the Secretary of Agriculture conjointly, consisting of five physicians, three of whom are to represent the Army, Navy and Marine Hospital Service, to be appointed by the President; a board of five experts, who are eminent in physiological chemistry and hygiene, to be appointed by the Secretary of Agriculture; and these together with the Chairman of the Committee on Pure Food Standards of the Association of Official Agricultural Chemists and the Chief Chemist of the Department of Agriculture of the United States, will form a board of twelve persons to whom all matters relating to wholesomeness of food products, or of materials added thereto, will be referred. It is evident that such an unbiased body will be able to reach conclusions, after proper investigations, which will merit the confidence of the country.

The administration of the law is confided to the Secretary of Agriculture, who is authorized to make all needful rules and regulations for carrying out the provisions of the act, and in doing this is to make use of the chemists and appliances of the Division of Chemistry of the Department of Agriculture. This method of administration has been approved of at all of the sessions of the Food Congress as being the wisest, most efficient and the most economical method of securing the purposes in view. The Secretary, at his discretion, can make use of the chemists and appliances of the various States engaged in food inspection, in order to render the service local, where the infringement of the law may have taken place.

The only element of discord in the Food Congress was developed by a proposal to establish an entirely independent food bureau, with an independent chemical laboratory, for the administration of the law. The head of this bureau, it was proposed, should be appointed by the President, for a term of four years, thus making the administration of the pure food law subject to frequent political changes. This provision was debated at great length for two days and at times with a degree of acrimony which indicated that some of the promoters of pure food legislation were more anxious to secure a new office than to establish a food law. At the end of this discussion the original plan, endorsed by previous Congresses, passed by a large majority and the bill thus approved was adopted without a dissenting vote.

On the third day of the Congress, by the invitation of the Committee on Interstate Commerce of the House of Representatives, a large number of the delegates attended the meeting of the Committee, at which the merits of the bill were presented in five minute speeches, by the representatives of the various industries attending the Congress.

In the interests of the public health and public honesty, it is to be hoped that the measure which has been recommended for the third time by this national Pure Food Congress, and which has the approbation of all the great trade interests of the country, will be pushed to a speedy vote and become a law before the present session of Congress adjourns.

---

*THE ACCURACY OF THE EXPERIMENTAL METHODS OF THE CHEMIST.**

On occasions like the present, where intellectual labor is the chief aim of those who are assembled together, it is a frequent practice for the speaker to offer to his audience something of the fruit which he has gathered from his own investigations. To the thought which lies at the foundation of this custom, are due those inaugural addresses which can lay just claim to being contributions to scientific knowledge. Other speakers prefer to furnish to these cultured circles a glimpse into the workings and tendencies of the higher institutions of learning. It were to me a great pleasure, esteemed colleagues and fellow students, could my efforts to-day draw me closer to you ; at all events this address shall serve as a greeting of welcome from the Rector, now entering upon his office, to all those who are connected with this *Hochschule*, and to all those who feel in it a kindly interest. And it is in this last sense that I beg leave to offer a few thoughts upon

THE ACCURACY OF THE EXPERIMENTAL METHODS OF THE CHEMIST.

It is the well recognized task of scientific investigation to discover the truth, and in those cases where this is not possible, to approximate it as closely as possible. In the natural sciences we may look upon this goal as attained when it is possible, in the broadest sense of the word *to describe* that which is appreciable to the senses. For this purpose it is generally insufficient merely to allow the object to act directly upon the senses, without in any way modifying its natural conditions ; we must avail ourselves of external assistance which either shall like a lens render our observations more accurate, or shall make possible the study of the object under changed outward conditions. On the one hand we use meter stick, balance, microscope ; on the other Bunsen burner, electrolytic cell, Röntgen apparatus, and the like. One need but cast a glance into the workshop of our investigator to see what an arsenal of appa-

* Inaugural address of the Rector of the Technischer Hochschule, Graz, Hungary. Translated by J. L. H.

ratus of both these classes stands at the command of the modern investigator in natural science ; literally numberless are the conditions under which matter is ever anew compelled to yield up its secrets.

Let us now look more closely at the work of the chemist, that we may learn how far the results attained by the methods at his disposal may lay claim to exactitude.

The task which we have proposed may be treated in different ways. We could from a general standpoint, discuss the criteria by which the accuracy of an experimental method is to be judged. A method will thus be valued as exact according to the concordance of the results attained by it on many repetitions or according to the concordance of these results with those attained by other methods. The fulfilment of this last condition is especially of value, and we shall therefore later recur to an especially interesting case of this kind. The value of a method moreover will be further increased if it is fitted to broaden the field of experimentation ; just as a piece of apparatus is of increased value, when it is adaptable for different experiments.

I prefer, however, to pass by these more general considerations and to discuss the exactitude of experimental methods in their bearing upon a few problems, whose fundamental importance is recognized. Of these I select three.

First we will consider the proof of the law of *indestructibility of matter*, as an example of the degree of exactness for which experimental data can be obtained, where the *determination of atomic masses* is concerned.

A second problem will be the *delicacy of chemical reactions*, under which it is to be considered, how far the accuracy of our apparatus allows us to detect the existence of definite chemical substances. And if both of these cases shall lead us to increased confidence in our methods, and we come to feel that the exactness of our experimental methods is very great, our third study on the other hand will serve to shatter this confidence. This study is that of *the absolutely pure substance*, and brings us at once to the point where the experimenter is wholly convinced of the justice of the conclusion that the hands of man can never bring into existence the unconditionally perfect.

Before we enter upon a consideration of these three examples, however, it will be well to notice the case which has already been spoken of, which reveals, as hardly any other could, the fact that those views, which have been attained by very different ways, and which we form from facts and phenomena upon the basis of sentient perception, may coincide to a remarkable degree ; this is particularly the case if we take into account the possibility that our observations may not correspond to the reality quite as closely as the investigator commonly claims. In determining the density of the vapor of mercury, if one proceeds on the supposition that all gaseous bodies under the same conditions of temperature and pressure contain the same number of molecules in the same space, he comes to the conclusion that the vapor of mercury contains in the molecule only one-half as many atoms as that of hydrogen. If, as appears from the volume relation in the analysis and synthesis of hydrochloric acid, this hydrogen molecule contains two atoms, it then follows that in the vapor of mercury the smallest particles which exist in a free state are single atoms. Now it is possible to reach this result by a wholly different method. It is a familiar fact that the velocity of sound may be used to determine the relation between specific heats of gases at constant volume and constant pressure. For this determination the knowledge of volume and weight is necessary, and besides this a measure of length, that is the length of the sound waves. The experiment furnishes us for this relation in the case of the vapor of mercury a higher value than in most gases. This ratio is one and two-thirds, that is, it is exactly the figure which is demanded by the kinetic theory of gases for a gas which contains a monatomic molecule, where the atomic energy of the molecule can be neglected when compared with that of the molecule as a whole. The velocity of sound in the lately discovered gases, argon, helium, neon, xenon and krypton, has also been found to correspond to monatomic molecules. This knowledge stands further in beautiful harmony with the chemical properties of these elements, whose atoms—apparently *without affinity*—appear unable to enter into any kind of combination. They seemed doomed to eternal solitude.

We now come to the first of the three problems which we have proposed for our consideration to-day. The question of the indestructibility of matter can best be introduced by recalling the investigations of the distinguished Belgian chemist, Stas, who attained an exactness in his work which has excited the admiration of all succeeding chemists. His investigations especially reveal where the experimental possibilities in this field find their limit. A closer view of his work would unfortunately compel us to enter upon a series of dry studies of figures. We will, however, take one example from among these. In order to prove our law, Stas prepared synthetically three quarters of a kilo of silver iodid, a quantity which the analytical chemist would consider enormous, and he found this weighed only fourteen and one-half milligrams less than the weight of the constituents of the compound. This is an accuracy reaching one fifty-thousandth part of the whole quantity. How extraordinarily close to complete agreement these figures lie may be judged when one considers that in our ordinary gravimetric methods, using perhaps a gram of substance, an error of one milligram may certainly be looked upon as small. This is an error of a one-thousandth of the whole quantity used.

As further experimental contributions to the law we are considering the work of Kreichgauer and that of Landolt is interesting. These investigators have carried on chemical observations in fused glass tubes in order to decide, by most careful weighing, these two questions: whether in a reaction, a ponderable portion of ether disappears or is added to the substances used; and whether the products of a reaction are influenced in exactly the same way by gravity as are the factors which enter into the reaction. Kreichgauer's experiments were calculated to detect a change in weight which would have amounted to one twenty-millionth of the mass present, but even this minute change of weight was not detected. In Landolt's experiments it was also impossible to detect any change in weight, although he did not consider the possibility of such a change absolutely excluded, chiefly because the variations, which were considerably less than one-tenth of a milligram, were always in the same direction.

In more recent times Ramsay and Rayleigh have carried out extremely accurate experiments. These distinguished scientific observers at first set before themselves merely the problem of determining, with the greatest possible accuracy, the weight of a few gases, among others that of nitrogen; but in the course of these investigations they came to the most unexpected results, for they were led to the discovery, and later to the separation of the unknown constituents of the air, argon, xenon, etc., as already mentioned. In such ways, an ever increasing perfection leads to ever more accurate results. And if it be true that in all investigations of this kind we must be denied the possibility of reaching the absolute truth, there is, nevertheless, infinite satisfaction in the consciousness that we may approach nearer and nearer to the goal. The experiments of Ramsay and Rayleigh, however, lead us also to the knowledge that with the perfection of our methods, there may follow also the discovery of wholly new facts; and so investigation and experimentation are always worth while. They also bring as a reward answers even more numerous than the questions proposed. In other words, as in other fields, so also in natural science, one advance seldom takes place alone. In this sense it is not just that we should so frequently speak of notable discoveries being made by accident; for we thus minimize the labors and the deserts of the experimenter in the minds of others who are not familiar with his work.

We pass now to our second example. Methods which have for their aim the qualitative detection of elements are, other things being equal, considered more valuable according as they are more sensitive, that is according as they lead one to his desired end with the use of the least possible quantity of substance. In this respect it seems to be almost universally accepted that the smallest quantity of substance can be recognized, not by special experimental apparatus, but directly through one of our senses—that of smell. On the one hand this assumption rests upon the observation of E. Fischer and Penzoldt, that the limit of perception of the odor of mercaptan is reached when one four hundred and sixty-millionth part of a milligram of the substance is present. On the other hand the work of Kirchhoff and Bunsen shows that by spectrum analysis one fourteen millionth of a milligram of sodium can be recognized with certainty. By this it is not to be understood that Kirchhoff and Bunsen submitted this quantity as the smallest amount of a given element which will suffice to give a spectrum recognizable with certainty, but they merely put forth this statement to show the superiority of the methods of spectrum analysis in general. My own observations, the details of which do not belong here, have at all events convinced me that it is easy to so extend in spectrum analysis the limit of sensitiveness that we must to-day look upon spectrum analysis as by far the most delicate of all analytical methods. It is possible for us to compare the smallest amount of detectible substance with the hypothetical mass of the molecule, that is with the smallest quantity of substance that is capable of existing. In this way we easily reach the perhaps surprising fact that the least quantity of mercaptan perceptible to the senses contains about 2×10^{10} molecules. Hence, even of the most penetrating odors, it is necessary for twenty billions of their molecules to bombard the olfactory nerves, before these carry the sensation to the brain; they utterly ignore all smaller quantities. In ordinary analytical methods the quantity of substance is naturally incomparably greater. Without undertaking to weary you with figures I will in general and briefly note that by micro-chemical methods it is possible to detect about one ten-thousandth of a milligram, while in ordinary test tube reactions, it is desirable to have at least several milligrams of the substance present.

And now we come to the consideration of the last of the problems mentioned. The processes by means of which we decompose the mixtures which nature furnishes us, into their individual constituents, that is obtain from them chemically pure compounds, are of many kinds. We make use of variations in solubility and volatility, of the possibilities of crystallization and diffusion, of chemical, electrical and magnetic relations. These are, in a single word, really gradual differences, which can be used so much the less perfectly as the bodies to be separated resemble each other in physical and chemical aspects. Purification thus appears a process that can only be worked by degrees, so that we can consider the absolutely pure body wholly as a limiting condition. In the natural sciences it is often desirable to obtain as closely as possible such limiting conditions: for example we may mention the absolute zero, the possibility of which is clearly deducible by a simple consideration of the law of Gay Lussac: the absolute vacuum, a conception usually derived from the fact that the quantity of substance in a given space can be more and more diminished; (we are on the other hand convinced with certainty that it is as little possible to obtain a true vacuum artificially as it is to conceive of it in interplanetary space). Again, the condition of absolute equality of temperature between two bodies in contact, or of a system which is in absolutely complete chemical equilibrium, are purely ideal limiting conditions, which, practically speaking cannot be attained. In this sense it is not possible for us to obtain any substance completely free from impurities, and we must therefore be contented to carry the purification as far as possible—a task with which chemist and physicist are employed. A few striking examples may be noted in this field, and especially those in connection with the name of Stas. At first for the purpose of carrying out his atomic weight determinations there was demanded exceptionally pure substances, and it was naturally necessary for him to devise the means of obtaining them. Later he took up the experimental proof of the problem which had been suggested by Lockyer as to the composite nature of certain metals, and for this purpose Stas prepared with the greatest care a series of pure salts. For example, after eleven years' labor he succeeded in preparing a specimen of potassium chlorid, in which it was not possible to detect by any means the slightest trace of sodium. The investigations of Kohlrauch and Heydweiller may be mentioned here. They undertook the preparation of pure water in order to be able to determine its electrical conductivity with the greatest possible exactness. These investigators were obliged to carry out their work in glass vessels, and under such circumstances we can but be astounded that they succeeded in obtaining water so pure that a liter contained the exceedingly small quantity of a few thousandths of a milligram of foreign substance. More recently W. Spring has been engaged in this same problem of the purification of water, and has thrown new light upon it. He has found that in all liquids which have been purified by distillation (that is, according to the methods commonly in use up to this time) small particles are still present which may be detected by optical methods, and which in some circumstances can be eliminated by an electrolytic process.

Thus these new and more accurate methods furnish results which now in one direction and now in another can be considered more exact, although the attainment of the limit, as already mentioned, must be regarded as impossible. In other words, we are not in a position to absolutely exclude from a given space which is filled with one substance a large number of other substances. Nevertheless perhaps, in a single instance it has been possible. To touch upon this briefly, we must notice the problem which has been handled with remarkable accuracy by Baker, an Englishman. Baker has set for himself primarily the problem of the relations of gases to each other in conditions of the greatest possible freedom from moisture. In passing it may be stated that these gases were kept in fused glass tubes for months in contact with the best drying substances, for example phosphorus pentoxid, and thereby acquired in most cases very remarkable properties.

Substances which in other conditions react upon each other with the greatest energy were perfectly indifferent. Thus the dangerous phosphorus, which generally takes fire in the air at a temperature somewhat lower than that of the body, can be distilled in oxygen ; and hydrochloric acid and ammonia gas can be mixed without indicating any reaction. How shall we reconcile these observations with our commonly accepted theories? Is there here an interval in the properties, and is this interval connected with a similar interval in the conditions; that is, have affinity and moisture here in fact become absolutely nil? It is indeed hardly necessary to assume that the affinity has become zero, for one can equally well account for the phenomena, if one assumes that the velocity of the reaction has diminished very greatly, as seems already to have been proved the case at very low temperatures and for a perfectly dry mixture of carbon monoxid and oxygen. Also against the assumption that in Baker's experiment the last molecule of water has been wholly removed may be cited the fact that the water which is contained in the metaphosphoric acid still possesses an extremely small vapor tension. Further, even if Baker's dried gases really undergo a sudden change in their chemical properties, it does not necessarily follow that at the same time a sudden change in the moisture shall be present. As a matter of fact, we know that the properties of matter often change in a very unexpected way when they are only in the vicinity of such a limiting condition. The electrical phenomena in tubes of high vacuum present a familiar example. From a theoretical standpoint the facts which have been mentioned, aside from the interest which they arouse from their strangeness, are also remarkable on another ground. This has reference to the different hypotheses which have been proposed as the cause of reactions. Among these we may note that of Armstrong, who assumes the presence of free atoms or ions and looks upon the conditions of reaction in gases, practically in a similar way to that demanded by the theory of Arrhenius and Ostwald for liquid electrolytes. By this the analogy which has been suggested between these two states of aggregation, and which at present dominates the thought in the province of inorganic chemistry, is rendered complete We may add to this that the remarkable observations, according to which gases under the influence of Röntgen and certain other rays become conductors just as if electrolytes, lead to the same conclusion. It shows us again in what close relationship the perfection of methods and of the experimental resources on the one side, and advancement in knowledge on the other, stand to each other. Experimental science and theory are a constant stimulus to each other and bring forth their fruit side by side.

And now I have come to the end of my proposed task. I have indeed spoken only from the standpoint of my own field; but I believe that the conclusions which are drawn from these considerations may be so far generalized that they appear of importance for the technologist also. The sciences on which his work rests are applied mathematics and applied natural science. The former can do its work wherever the latter has by experiment laid a foundation, and because thus in the improvement of methods and appliances results are being attained which are of increasing value, the technologist may take an interest, we may almost say an egotistic interest, in the successful development of the pure natural sciences. One thing further, of a more ethical nature may be suggested by the fundamental similarity of the problems in both departments. Just as we chemists labor to come as close as possible to the absolutely pure substance, or to some numerical value (atomic weight and the like), in the same way the machine builder strives for the conveyance of energy with the least possible loss, and the engineer for the lightest possible carrier.

And if indeed, the complete solution of these problems lies beyond the scope of our powers, if from the side of nature the inexorable 'No' stands against us; nevertheless, we have in our hands in the increasing accuracy of our methods of work the true philosopher's stone, by means of which we can ever come nearer and nearer to our goal. Let us look upon the creation of new methods of experimentation and the improvement of the old methods in our practical science, as one of the most important duties for those who seek for progress and see in the development of our powers of reason the foremost task of the cultured mind.

FRIEDRICH EMICH.

GRAZ, HUNGARY.

CORRESPONDENCE OF C. S. RAFINESQUE AND PROFESSOR WM. WAGNER.

IN hunting through the natural history material collected by the late Professor William Wagner in the Wagner Free Institute of Science, some fourteen years ago, I discovered several letters from the eccentric naturalist Rafinesque, together with a number of pamphlets written by him.

Professor Wagner had evidently taken up Rafinesque upon his return to Philadelphia from Kentucky with all the enthusiasm that a man interested in the development of the study of natural history must have for one who gave his whole time and all the money he could scrape together for the amassing of collections in every department of zoology and botany. It would appear from the context that Rafinesque had got into trouble (no unusual thing for him) and wished Professor Wagner to go on his note for the amount necessary to relieve him. This was promptly refused for the reasons given in Professor Wagner's letter, and Rafinesque writes to him on the 10th of April, 1840, as follows:

DEAR SIR:—I wish you will send me five dollars at y'r convenience for my 'Amenities of Nature' or at least One Dollar for the first Number that you have already had—that is the price. The value of Montford is $10. having 261 plates & with my notes $12. to 15; while Mantell is only worth $3.

I sell my works, my shells, my drawings and my services—I give them away sometimes to particular friends only, altho' I can hardly afford it.

Yours, &c,

C. S. RAFINESQUE.

Professor Wagner immediately replied on the 10th of April, 1840:

DEAR SIR:—Your note of this morning I found on my table on my return home at noon.

Your singular request to send you five dollars "at my convenience for your 'Amenities of Nature,' or one dollar for the one you say I have rec'd really surprises me. I now return to you unread, as my time has been otherwise much occupied that which you loaned me for my perusal and to which I never subscribed. If you have done perusing my copy of Mantell which, you informed me, you had read with interest & pleasure, you will please hand it to the bearer, as I wish to lend it to other of my friends. You inform me you sell your works, shells, drawings & services. I would beg leave to remark I have no occasion for any of them at present. You add "you give them away sometimes to particular friends only." I would add if you intend the remark for me you must know I never asked you for anything, neither have I ever received an atom of any of your property or effects, no not the most trifling, neither do I want them. I really regret my refusal yesterday to enter the requested security has produced an ebullition of feeling as your note indicates. I would have thought that your age and philosophy would have controlled your passions particularly after my explaining my reasons.

Yours, &c,

WM. WAGNER.

The reply from Rafinesque is dated April 12, 1840, and reads as follows:

MR. WILLIAM WAGNER.—The work of Mantell was delivered to your servant as you requested. I am used to disappointments—it was not an angry feeling but *sorrow* I experienced at your refusal;

sorrow that I had been mistaken in hoping I had acquired another learned friend. I had anticipated much pleasure from the study with you of the shells and fossils of y'r fine cabinet, as you tendered—you may now have that pleasure alone. I wish Conrad, Troost and others may be found willing to give you for nothing the use of their labors and discoveries, as I had proposed for my own; but I doubt it; Few are as liberal as I am. As you neither require my works, nor shells, nor fossils, nor labors *now*, I have wondered why you asked them before.

My time will thus be better employed perhaps in continuing my solitary labors. It is a pity that here naturalists will not be friends and labor jointly to increase knowledge. When you return from your intended travels we may resume joint studies, if you require it.

Respectfully yours,
C. S. Rafinesque.

On the 16th Professor Wagner writes:

Your note of the 12th was handed me this morning only. You still harp upon the disappointment you reced in my refusal to enter bail as you stated for your appearance only to prosecute an appeal which in reality was bail for debt, squire fees, court expenses, etc., in case of final defeat. If your boisterous manner and final departure without an ordinary adieu expresses sorrow (& what I considered anger) why you show your feelings very differently from anyone I ever saw. I expressly informed you I was retiring from business and this day we have advertised our stock for sale at auction and I have resolved that I would not contract any new liabilities, that I was closing everything and would avoid all new responsibilities. Any reasonable man would not have murmured at such an explanation. My article of copartnership independently of all other objections positively precludes my complying with your request. I regret that you should have thrown the obstruction in the way of our scientific intercourse and assure you that I was as much pleased with our friendly interchange of thoughts and opinions as you could possibly have been. You have caused the breach. Therefore it is for you to close it if you desire it. You again speak of giving for nothing your labor, your discoveries, etc. I never received any of your labors, or discoveries, or anything else. If you can show I have, send me a bill of it and I will pay your demands. The only transaction we have had was that I loaned you a book and you loaned me one. I cordially agree with you that any interruption of our joint studies by your extraordinary request is as disagreeable to me as it can be to you.

Respectfully yours,

The last letter comes from Rafinesque under date of the 17th of April, 1840.

Sir:—Y'r letter of yesterday did not require immediate answer, but having received two important letters from European geologists which under other circumstances would have been immediately shown to you, it may be proper to impart some of their contents. My Geological Fragments have been published by the first Geological Society of Europe. I am informed that American fossils (particularly of the oldest formations) are very scarce in European collections and wanted for sale and exchange. I am instructed to apply to you and others for specimens but all of mine are required. Muchinson (?) and a friend of mine are going to publish jointly the whole silurian system of Europe and all such American fossils of that age they can procure, therefore as you have stated you no longer want my fossils and have perhaps given up y'r idea of undertaking the American silurian system—I propose to send to Europe this year the whole of my American fossils amounting to thousands and of great value—of which it is proper you should be apprized in time. If you should go to Europe instead of the South and West and carry your fossils there, I will be able to inform you further. I shall no longer *harp* as you say on my disappointment I have merely to remark that as a candid man I prefer a direct refusal to pretext. That you may be undeceived ab't your apparent surmise, I must add that I don't owe one dollar to anybody, and pay all just demands. It was never stated that you received any of my labors and I don't send false bills to anyone. My herbarium was all around us at my office and you never asked to peep into it. My fossils and shells are in boxes as I cannot spend large sums like you to display them. They have been tendered for drawings only at y'r own request, a great favor you ought to know; but next year shall be in Europe where valued and paid for in the equivalents. As I have many duplicates if you will exchange them immediately with some of y'rs I have no objection—Price for price.

Respectfully y'rs,
C. F. Rafinesque.

These letters would seem to be almost childish but for the fact that Rafinesque had been for several years thoroughly eccentric in his actions and this was probably the beginning of the miserable end.

They were probably written when he lived on Race Street in a garret. If he died on September 18, 1840, as is stated by R. E.

Call in his 'Life and Writings of Rafinesque' these must have been written but five months before his decease and his quarrel with Professor Wagner probably ended his scientific associations in this City.

In looking up the date of his death I have been struck with the fact that Lippincott's Biographical Dictionary, Simpson's 'Lives of Eminent Philadelphians' and Appleton's Cyclopedia of American Biography quote the date of his death as September 18, 1842 and the National Cyclopedia of American Biography is the only authority that I can find for the year 1840, which is used by Call.

THOMAS L. MONTGOMERY.
WAGNER FREE INSTITUTE OF SCIENCE,

---

*SOME OBSERVATIONS CONCERNING SPECIES AND SUBSPECIES.**

SOME few weeks ago I gave to this Society a brief general account of the investigations which the Fish Commission carried on at Lake Maxinkuckee during the past summer and fall.

At this time, I desire to speak briefly concerning two new fishes obtained in these investigations, and certain questions concerning species and subspecies which their study has suggested.

In the first place, permit me to repeat some of the statements regarding the lake and its small tributary streams.

Lake Maxinkuckee is located in the southwest corner of Marshall County, Indiana, on the Logansport and Terre Haute railroad, 32 miles north of Logansport, or 34 miles south of South Bend, Indiana. It is about 2.75 miles long, from north to south, 1.75 miles wide, and is quite regular in outline. This, like all the lakes of northern Indiana, is of glacial origin. Its greatest depth, so far as known, is 86 feet. The bottom is of compact sand and gravel near the shore, then a wide bed of marl, and soft mud in the deeper parts. There are only 1 or 2 short reaches near the shore where the bottom is soft. The water is relatively pure and clear. The bottom temperature in summer is 47° to 50° Fahr., while the surface gets as warm as 77° to 80°.

The lake is well supplied with aquatic vegetation; *Chara*, *Potamogeton*, *Myriophyllum*, *Ceratophyllum*, *Nitella*, *Vallisneria* and *Scirpus* being abundant. At least ten species of *Potamogeton* occur and two species of *Scirpus* are found. *Chara* is very abundant, great beds of it covering the bottom in many places from near shore out to a depth of 12 or 15 feet.

The catchment basin of the lake is small. There are no tributary streams except one very small brook at the south end, a somewhat larger one at the southeast corner, and three small ones upon the east and northeast sides. The total amount of inflow from these little creeks is but a few gallons per minute. They are all short, sluggish streams and do not vary greatly in size at any time. Perhaps the only ones deserving mention are (1) the one at the southeast corner which is popularly known as 'the inlet,' (2) one near the middle of the east side, and (3) one at the northeast corner flowing into Culver Bay, and which has come to be known as Culver Inlet. The stream on the east side has been called Aubeenaubee Creek, from the Pottowattomie chief of that name who at one time owned the land on the east of the lake. It was from this small creek that the specimens of the new species were obtained. Aubeenaubee Creek does not exceed 1.5 miles in length. It has its source in a small marsh, and is a sluggish stream flowing through a low, level meadow or prairie region. It is about 4 feet wide and averages only 3 to 6 inches deep, with deeper holes at intervals. Through most of its

* Read before the Washington Biological Society, Jan. 26, 1900.

length the stream is overhung by bushes and briars, and is full of sticks and brush. The bed and banks are of black mud with a mixture of sand. In some places the ground is quite boggy. The midday summer temperature of the water in this stream is about 72°. The species of fishes found in this stream are almost wholly different from those found in the lake proper, a fact illustrating clearly the importance of even slight differences in geographic location if accompanied by stable environmental differences. The principal fishes occurring in this creek are *Semotilus atromacalatus, Campostoma anomalum, Umbra limi, Lucius vermiculatus, Notropis cornutus*, and young *Micropterus salmoides*. Crawfishes were abundant.

The two new fishes discovered are both darters, one belonging to the genus *Hadropterus* and the other to the genus *Etheostoma.*

I may say, in passing, that the darters are members of the Percidæ or Perch family, to which belong the walleyed pike, the Sauger and the Yellow perch. Sixteen genera and 85 species of darters are recognized. They are all small, active fishes, usually brilliant in coloration and have much the same position among fishes that the warblers have among birds.

Both of the new darters obtained at Lake Maxinkuckee were found in Aubeenaubee Creek and nowhere else.

The nearest relative of the species of *Hardopterus* is *H. scierus*, which, though not known to occur in Lake Maxinkuckee, is found in Yellow River of the Kankakee drainage, only a few miles north, and also in Tippecanoe River five miles south of the lake. The form found in the creek is well set off from its nearest relative and is described as a species.

The other darter, described as new, is evidently derived from *E. iowæ*, which is found, not only in many of the streams of western Indiana, but also in Lake Maxinkuckee in some abundance. It is, however, not known to occur in Aubeenaubee Creek.

Etheostoma iowæ, in extending its range from its original center of distribution, in all probability, found its way into Lake Maxinkuckee from the Tippecanoe River. Having once become established in the lake, individuals sooner or later began entering its tributary streams. Among the individuals entering Aubeenaubee Creek there were some that, finding the conditions easy, remained and bred there, and thus a creek colony was established. It is altogether probable that for some, possibly many years, individuals from the colony would occasionally return to the lake and interbreed with individuals that had never left the lake. And the reverse would also take place: individuals from the lake would probably continue for many years to invade the domain of the creek colony and interbreed with its members. Under conditions such as these, the members of the colony going farthest toward the head of the creek were probably the ones which soonest became free from the influence of the lake and, breeding only among themselves, were modified most rapidly by the new environment. In time they became so well differentiated as to render them readily distinguishable from the parent form in the lake. During the continuance of the conditions mentioned, however, the migration and countermigration between the lake and the stream, there would be found in the lower part of the stream and in the lake about its mouth, the progeny of the individuals from the lake and creek which had interbred. These would possess characters more or less intermediate between the parent species (*E. iowæ*) and the derived form inhabiting the creek. So long as these intermediate forms continued to exist, the form found in the creek would be only an incipient species. As an incipient species it would be a subspecies of *E. iowæ*, and would receive a trinominal name.

But if, in the course of time, invasions of one habitat by individuals from the other should cease, then the intergrading forms would, through interbreeding with the extreme forms, be gradually absorbed by them and finally disappear altogether. In the creek would then be found a form differing clearly and constantly from the lake form and without any connecting forms. Under these circumstances the form in the creek, as well as that in the lake, must rank as a distinct species.

This is the present condition, so far as our investigations have enabled us to determine. There is no difficulty in distinguishing individuals taken in the lake from those found in the creek, and neither form seems to invade the habitat of the other. Large collections were made, not only of the fishes inhabiting the lake, but also of those in the creek. The latter was carefully seined twice, from its source to its mouth, and not a single example of *E. iowæ* or any form showing intergradation was seen. Similarly careful investigations were made in the lake without discovering any individuals of the creek form or any showing intergradation. Whether further collecting will discover connecting forms cannot, of course, be stated. The small size of the creek and of the lake, and their close geographic relation, render it almost certain that individuals of the one form would occasionally invade the habitat of the other, and *vice versa*. While the environment of the creek is markedly different from that of the lake, it is improbable that a change from one to the other would prove disastrous to the individuals concerned. Some of such individuals would, it seems, be able to survive, and some would probably interbreed with individuals of the other form whose habitat they had invaded. This was, quite likely, the condition in the beginning, and the creek form, so long as it remained connected with the parent species by the intergrading forms resulting from such interbreedings, would be a subspecies of the parent species. But, as already stated, no such connecting forms have yet been found and the form inhabiting the creek is a distinct species.

There is one other possible condition worth considering. Let us suppose that, after the creek colony had become well established, and for many generations had not intermingled in any way with the parent species in the lake, the habits of one or the other, or both, should change somewhat and that they should again begin to invade each other's habitat and to interbreed. The result of this interbreeding would be the appearance of individuals possessing morphological characters more or less intermediate between the lake and the creek forms. In other words, individuals would be found showing that the two forms intergrade and placing them again in the relation of species and subspecies. If we could *know* this to have been their history, however, we should certainly not place them in the relation of species and subspecies. We should regard them as two distinct species, and the individuals which seem to show intergradation we would call hydrids, which they really are. But we can rarely, if ever, *know* that such has been the history. So long as intergradations are found connecting the two forms, the one last discovered must be regarded as a subspecies of the other. In the present case, however, no intergradations seem to exist, and the relation is that of two distinct species. While the occurrence in nature of hybrids is doubtless very unusual, such a condition as the one supposed is certainly not improbable.

And this suggests a further consideration of subspecies. An examination of the descriptions of forms which have been published as subspecies does not show that the describers have all been governed by the same principles, or that all who have described subspecies have had very well-defined ideas as to what a subspecies really is. I am sure that I myself have given trinominal names to new forms with rather hazy ideas upon the relation of species and subspecies.

The present practice of most systematists in this country seems to be to regard any two given forms as distinct species, unless they are known to possess morphological characters which intergrade. If characters showing intergradation are present, the one later described is regarded as a subspecies of the other. The intergrading may be of two kinds of categories:

1. It may be associated with the known joining of the two respective habitats. In this case the individuals possessing the intermediate characters would come from the region where the two forms, or the habitats of the two forms, join or overlap. If *E. iowæ* were known to intergrade with the *Etheostoma* of Aubeenaubee Creek, the connecting forms, if of this category, would be found in the mouth of the creek, or in the lake near the mouth of the creek. This, it seems to me, would be a good example of what we mean by a subspecies.

2. In the other case, the two habitats do not join, but an examination of a series of specimens from each will show an intergradation of characters. Though the sum total of the characters is different, individuals will be found in one series which possess, in varying degree, all the characters shown by those of the other. The individuals showing the intergradation come from the same localities from which have been obtained the typical individuals. They do not come from intervening localities because the habitats do not join.

Is it correct to regard these two forms as sustaining the relation of species and subspecies?

Trinominal names have, in many instances, been given because the differences separating the form under consideration from some previously-known form are slight. But now, the almost uniform practice seems to be to regard constant differences, however slight, in the absence of known intergrading forms, as of specific value; and differences, however great, if known to intergrade, to be only of subspecific value.

If this view be correct, there are many trinominals in current faunal and floral lists which are there without sufficient warrant. In the latest systematic work on American fishes 3255 species and subspecies are recognized. Of these, 125 are ranked as subspecies. But an examination of the facts regarding each shows that very few of them should stand as subspecies, but as species. They have, in most cases, been called subspecies simply because they differed but slightly from the most closely related species. I doubt if intergradation is *known* to exist in 25 per cent. of the cases.

I have been told that many of the trinominals in current use in ornithology rest upon the same insufficient evidence.

It is the practice of some, I believe, to describe as subspecies forms which, though not *known* at the time to intergrade, will in all probability, be found to do so. The describer's knowledge of the group to which they belong, the principles of geographic distribution, and the geography of the country in which they are found, justify him in anticipating the evidence of actual intergradation.

Personally, I doubt if this is the best course to pursue. Would it not be better, either to wait until the evidence is in hand, or describe the new form as a species?

We sometimes hear the remark that systematists often go too far, and describe as new species or subspecies forms which differ but slightly from known forms; that they give specific or subspecific value to differences which are due merely to some slight difference in environment. This, it seems to me, misses the whole point. What produces species and subspecies, anyway, except slight differences in environment, together with greater or less geographic isolation? And when we see these differences why should we refuse to admit their existence or their meaning?

BREATHING OXYGEN.

The experiments here described were carried out during the course of an investigation to determine the quantity of carbon dioxide exhaled from the lungs of different persons under stated conditions.

The method of procedure was as follows: (1) Ordinary air was inhaled through the nostrils and exhaled through the mouth (the nostrils being closed) into an inverted receiver filled with water. The quantity of carbon dioxide in the exhaled gases was determined in the usual manner. (2) A mixture of air and oxygen containing 26.4 % of oxygen was inhaled and exhaled as in (1). (3) Pure oxygen was employed and the experiments conducted as in (1) and (2).

The breathing experiments were made by three different persons, A, B, and C, under conditions as nearly indentical as possible. The following results were obtained:

A		B		C		
Exp.	CO_2	Exp.	CO_2	Exp.	CO_2	
1	3.8	10	3.6	19	3.8	Ordinary air.
2	5.2	11	4.4	20	5.1	
3	5.6	12	4.6	21	5.8	
4	4.0	13	4.0	22	4.0	Air and oxygen.
5	5.6	14	5.2	23	5.4	
6	—	15	5.6	24	5.6	
7	4.2	16	4.8	25	4.4	Pure oxygen.
8	5.8	17	5.6	26	5.8	
9	6.2	18	6.2	27	6.4	

The figures given express percentages by volume; they are lower than those that would be obtained if the exhaled gases were collected over water saturated with carbon dioxide. The object of the experiments was to get relative rather than absolute values. In experiments 1, 4, 7, 10, 13, 16, 19, 22 and 25, the gas (air, mixture of air and oxygen, or oxygen) was inhaled for five seconds and then exhaled for five seconds.

In experiments 2, 5, 8, 11, 14, 17, 20, 23 and 26 the lungs were inflated as fully as possible with the gas, which was retained *fifteen* seconds and then exhaled.

In the other experiments, 3, 6, 9, 12, 15, 18, 21, 24 and 27, the lungs were fully inflated and the gas retained *thirty* seconds before exhalation.

THE SOCIETY OF AMERICAN BACTERIOLOGISTS.

The following are abstracts of papers read at the first meeting of the Society of American Bacteriologists, held at New Haven, December 27th to 29th.

Natural varieties of Bacteria: Professor H. W. Conn.

Professor Conn exhibited some cultures of a highly variable Micrococcus which he had isolated many times from milk. Its color ranged all the way from a snow white to a deep orange, and in power of liquefying gelatin it ranged from a form that liquefied with great rapidity to one that had apparently no liquefying power. All these varieties, with numerous intermediate stages, have been found in nature and are not the result of cultivation. Professor Conn showed, however, what a great change can apparently be produced in the character of a species, by a simple process of selection. Starting with a pure culture of this organism, he was able to produce from it a white and an orange culture, by simply replating many times, and selecting the whitest color, on the one hand, and the yellowest, on the other. At the same time, by selecting the colony which liquefied most rapidly and the one which liquefied most slowly, he was able to obtain from the same original culture, rapidly liquefying cultures, and those with hardly any liquefying power. He raised the question whether many of the changes which had been described as due to changed environment, might not really be due to such unconscious differentiated selection.

The significance of varieties among Pathogenic Bacteria: PROFESSOR THEOBALD SMITH.

In the study of bacteria, morphological details are of but little value in differentiating and classifying forms because of their minuteness. Processes of conjugation and other sexual phenomena, such as are found among Protozoa, are unknown.

The problem of variation may be discussed under these heads:

1. The actual existence of bacteria whose relationship is conceded, although they manifest slight differences among themselves.

2. The artificial modification of bacteria by experiment.

3. The evolution of parasitic from saprophytic forms.

In the investigation of problems of this character it is necessary to study, not only the effect of related bacteria on the same host, but that of the same bacteria on different hosts. Our investigations should be both experimental and comparative.

(The variations occurring in the group of bacteria of which the rabbit septicæmia bacillus is the type, and those occurring in the pathogenic derivatives of the colon group, were discussed and illustrated. Variations among tubercle bacilli, in form and virulence, and among diphtheria bacilli, in the production of toxin, were also referred to.)

The modifications which bacteria undergo, during passages through animals, vary in degree with the species and group under observation; with some, such as the rabbit septicæmia bacilli, streptococci, and pneumococcii increase in virulence is easily attained; with the colon group this is much more difficult. The degree of change that can be impressed upon any bacteria probably depends largely on the specific structure of the organism.

The evolution of parasitic from saprophytic forms is a very slow and gradual process, whose mechanism may have differed with different species. Special advantages which a certain environment may offer for frequent passages through susceptible species may give certain saprophytes an impulse towards a parasitic existence. In any case, such saprophytes probably possess from the outset certain fighting characters, such as the power to produce toxins which enable the few among the myriads of forms, eventually, to become disease germs. (Published in the *Journal of the Boston Society of Medical Sciences*, January 16, 1900.)

Methods employed in the teaching of Bacteriology: PROFESSOR H. C. ERNST.

In response to a circular letter sent to the Institutions of Learning that teach medicine, as given in the 1899 volume of *Minerva*, there were returned ninety-eight replies. The letter asked for information as to whether Bacteriology was taught as a separate branch—in case it was not, in what department it was included—how many instructors were engaged in teaching this subject—the hours required—and other details of interest. It was found that forty-two institutions give instruction in Bacteriology as a separate department—twenty-six give separate courses, in connection with the department of Hygiene, and thirty-seven in connection with the department of Pathology, or Pathological Anatomy.

The increase in the numbers of teachers

of bacteriology in connection with medicine was noted, over the condition as found in the first volume of *Minerva* (1892).

(The full details of this investigation will be found in the *Journal of the Boston Society of the Medical Sciences*, Vol. IV., p. 67 et seq.)

On the changes of opinion in England in favor of bacterial purification of sewage: PROFESSOR L. P. KINNICUTT.

Professor Kinnicutt described recent experiments conducted in England which are producing a change in opinion as to the best method of treating sewage. Whereas, hitherto the chemical method of treatment has been commonly used, the belief is now rapidly gaining ground that the purification of sewage by bacterial growth offers the cheapest and most efficient method of purifying it so that it may be discharged into rivers without polluting them.

Recent work on sewage purification involving bacteria: H. W. CLARK.

The paper brought out clearly the fact that the benefit derived from preliminary anærobic bacterial action upon sewage before filtration has been recognized at the Lawrence Experiment Station for several years, and calls attention to statements made, and investigations upon this point recorded in the reports of the Station for 1895 and 1896 (see report of Massachusetts State Board of Health for these years). It gives credit to Cameron for first practical use of anaërobic action with his septic tank at Exeter, England. Results of investigations upon production and purification of septic sewage at the Lawrence Experiment Station during 1897 and 1898 were given, with a comparison of intermittent sand filters and bacterial or contact filters. Rates of filtration of septic sewage, equal to 300,000 gallons per acre, have been attained with sand filters at Lawrence, and of 800,000 with contact filters, with satisfactory purification. Investigations at Lawrence during 1898 have shown that open septic tanks are as successful as those made air-tight, owing to the scum of bacterial growths, fat, etc., formed over the surface of the sewage. Some experiments made at the Station seem to indicate strongly that anaërobic action may be carried to such a point that the resulting sewage is very difficult to purify.

The paper also gave the result of an experiment in which sewage during 1898 was passed through a filter of broken stone ten feet deep, at the rate of one million nine hundred thousand (1,900,000) gallons per acre daily, with very satisfactory results, nitrification being active, purification satisfactory, and the rate of filtration more than twice as great as ever before attained at Lawrence with crude sewage.

The significance of the appearance of B. Coli communis in filtered water: H. W. CLARK and S. D. M. GAGE. (Read by H. W. Clark.)

The purification of polluted waters by sand filtration has been studied at the Lawrence Experiment Station for the past thirteen years. Up to the beginning of 1897 the efficiency of the filters in removing bacteria was ascertained by determinations of the actual number of bacteria in the water applied to the filters and the effluents from them. For the past three years determinations of the number of *B. coli communis* in the applied water and effluents have been made. Especially has the efficiency of the Lawrence City Filter in removing this germ from the Merrimac River water been carefully followed. This was done, as it was believed that the significance of the appearance of the germ in the filtered water could be determined because of the opportunity presented of studying its appearance in connection with the occurrence or non-occurrence of cases of typhoid fever in the city of 55,000 inhabitants using this filtered water.

This city filter was built in 1893, and, while the death rate from typhoid fever in Lawrence for a number of years before its construction averaged about 12 per 10,000 inhabitants; the first year after construction the rate was 4.75 per 10,000 inhabitants, and this was followed by a steady yearly decrease to 1.39 in 1898. During this period there was no unusual disturbance of the sand filter bed, and its bacterial efficiency was good.

In the fall of 1898 it was necessary to relay some of the underdrains of the filter, and some of the sand beds were very much disturbed. When the sand was replaced and water was again passed through the filter the entire effluent was pumped to the reservoir and used in the city. Following the conclusion of this work, *B. coli communis* was found in 1 c.c. of 72 per cent. of the samples of the effluent of the filter examined during December; 54 per cent. of those examined during January; 62 per cent. of those examined during February; and 8 per cent. of those examined during March. The bacterial efficiency of the filter, or percentage removal of total numbers of bacteria in the applied water, was 92.20 per cent. from December 10th to 31st; 98.31 per cent. in January; 98.17 per cent. in February; and 99.89 per cent. in March.

During the period from the end of the disturbance of the filter in December until the end of the month there were twelve cases of typhoid fever reported in the city; during January, 59 cases; during February, 12 cases; but in March, when *B. coli communis* had practically disappeared from the effluent of the filter, there were but 9 cases, and these during the first portion of the month; that is, during the months of December, January and February there was an epidemic of typhoid fever in Lawrence. During this period, *B. coli* was present in 1 c.c. of samples of effluent of the filter examined to the extent denoted by the figures given. When it failed to be found in 1 c.c. the epidemic had ceased. When 100 c.c. of the effluent were examined, *B. coli* was found more frequently, but the figures and facts in regard to the epidemic seem to show that, when filtering a river water as polluted as that of the Merrimac, it is safe to assume that, when *coli* is found only infrequently in 1 c.c. of the effluent, the typhoid germs, necessarily fewer in number, and more easily removed by the filter, have been eliminated from the water. The death rate of the city from typhoid fever in 1899 was 3.00 per 10,000 inhabitants.

On the detection of bacillus Coli communis in water: Professor E. O. Jordan.

The direct application of the fermentation tube method to greatly polluted waters sometimes meets with a serious difficulty. This is the fact that other gas-forming species (and perhaps some non-producers of gas) overgrow *B. coli* and obscure or falsify the typical reaction. This appears to happen at least with some river waters more commonly than has generally been supposed, even when extreme dilutions are employed. One species that interferes often with the growth of *B. coli* is a variety of *B. cloacæ*, and when mixtures of pure cultures of this microbe and of *B. coli* are introduced together into fermentation tubes, the former frequently gains the upper hand.

A method that has given promise of overcoming this difficulty, and some others, is the following. The desired quantity of water is incubated in acid carbol broth, 1. c.c. of the required dilution being added to 5 c.c. of broth made 5 to 5.5 acid on Fuller's scale, and containing carbolic acid in the proportion of 1–1000. After inoculation at 38°–40° for 12 to 18 hours, platings are made in litmus lactose agar, and colonies reddening this medium are tested for coagulation of milk, indol production, liquefaction of gelatin, and gas production in glucose broth. A recent comparison of the two methods has given the following results:

	Positive results.	Negative results.
Fermentation tube direct	21	34
Acid carbol broth	26	24

Although the number of experiments is small, the results indicate the distinctly greater delicacy of the latter method when applied to the waters used in these tests. The application of this method is interfered with, to some extent, by the same species that complicates the result in the fermentation tube, but the use of the litmus lactose agar facilitates the separation of *B. coli*, especially if the plate be examined within 24 hours after the sowing.

Demonstration of Actinomycosis and the Causative Fungus: PROFESSOR H. C. ERNST.

A specimen of very marked affection of the udder with the Actinomyces fungus was reported. Attention was called to the comparative rarity of the disease in this marked form, and the fact that the textbooks say but little about it as a possible source of infection. A number of microscopic preparations were demonstrated. (This case is also to be published in the *Journal of the Boston Society of the Medical Sciences*, Volume IV.)

A comparison of B. Coli communis from different species of animals: V. A. MOORE and F. R. WRIGHT. (Read by F. R. Wright.)

Different forms of *Bacillus coli communis*, from contaminated water supplies and variations of the same organism in tissues of different species of animals, have led to this investigation to determine the range of variation of *Bacillus coli communis* in (1) different species of animals, and (2) in the same species, always under supposedly healthy conditions. As the work was not begun until late in the summer, this paper is to be regarded only as a report of progress.

The methods which were followed were:

(1) To take a loop-full of the mucus from the large and small intestines and inoculate a series of gelatin plates from each.

(2) To make sub-cultures from six typical spreading colonies which appear the same.

(3) To replate from these sub-cultures, to make sure of no contamination.

(4) From the second series of plates to make sub-cultures in the special media.

(5) To determine the pathogenesis by inoculating such experimental animals as the rabbit and guinea pig.

Thus far the results have shown that the organisms found in the horse, the dog, the cow, the sheep, and the hen, are more numerous in the large than in the small intestine.

The number of colonies from the same part of the intestine of the same species varies much, *e. g.*, in the large intestine of the horse, in some cases the colonies have been too numerous to count; again, there have been four or five hundred, and again, no more than a dozen. Where the number of *colon bacillis* was greatest, other species were few; where they were few, either a fungus or a micrococcus predominated in numbers. The most marked variations in the organism from the different species have been in the changes which they produced in milk, and in the various sugars and in their pathogenesis. The range of variation of the bacillus from the same species of animals has been found to be narrow.

The invasion of the Udder by Bacteria: ARCHIBALD R. WARD.

The extent to which lactiferous ducts of the cow's udder are invaded by bacteria, was determined by means of bacteriological examinations of the udders of nineteen freshly slaughtered milch cows. Owing to the prohibitive expense of studying the udders of sound cows, it was deemed expedient to use those of cows slaughtered after condemnation by the tuberculin test. So far as possible, the udders of only slightly diseased cows were used. Samples of the fore milk were taken, and before slaughtering, the udder was milked as thoroughly as possible. The udder was removed from the carcass immediately after death and taken to a sheltered spot, for the bacterial examination. In each quarter in successson, a flamed knife was used to make an incision extending from the dorsal to the ventral region of the gland, and of such depth as to expose the tissue in the vicinity of its vertical axis. Bits of the glandular tissue were transferred with aseptic precautions to tubes of gelatin, and properly labeled to show the region from which the culture was made. After returning to the laboratory, the gelatin was liquefied at a gentle heat and poured in Petri dishes. By comparing the colonies appearing on the plates after several days, with those in cultures made from fore milk, it was possible to show that the same organism may occur in the fore milk in all parts of the udder.

The evidence appears to warrant a modification of the statements concerning the place at which milk first becomes contaminated by micro-organisms.

The writer concludes that, while milk is sterile when secreted, it may immediately become contaminated by the bacteria which normally inhabit the lactiferous ducts of the udder. (Published in Bulletin 178, Cornell University Agriculture Exper't Station.)

Exhibition of cultures and stained specimens of plague bacillus from two cases of Bubonic plague admitted to New York harbor, November, 1899: WM. HALLOCK PARK, M. D.

Three slides were shown. The first was from a twenty-four-hour agar culture showing, among rather short thick bacilli, peculiar long thick thread forms. The second was from a twenty-four-hour bouillon culture showing short almost coccus forms in chains. The third was from the spleen of guinea pigs dying of septicæma, showing characteristic darker staining of the ends of the bacilli. Cultures were also shown on agar and gelatin. These cultures were of especial interest in that they were obtained from two persons, the captain and the cook, who arrived on a steamer from Santos, Brazil, in December, 1899, where the plague was prevalent. The two men when they arrived showed simply a large bubo in the lower inguinal glands. The temperature was nearly normal, and they did not feel ill. They had been sick about eleven days. They obtained the infection from a companion who had died and whom they nursed. Pus was removed from these bubos with a hypodermic needle. The pus from both cases contained the bubonic bacilli although in small numbers either living or dead. In culture they grew exactly like two other cultures which Dr. E. H. Wilson had obtained from India. Their violence was slightly greater than Dr. Wilson's cultures.

Some suggestions on the study of systematic bacteriology: FRED'K D. CHESTER.

Attention is called to a work now in progress in the arrangement of the better known species of bacteria. Certain typical forms or species of bacteria exist. These latter present certain definite morphologic, biologic, cultural, and perhaps pathogenic characters, which establish the types, independent of minor variations.

The most marked of these types become the centers of groups, around which are gathered related species and varieties.

Migula's system is followed as the basis or generic classification.

Tables were shown, giving arrangements of the bacteria in groups.

The necessity of some system of terminology for use in descriptive bacteriology was urged, and a table of definite terms presented. The question of nomenclature of species was discussed. Little or no regard has, in many instances, been paid by bacteriologists to the most ordinary rules of botanic nomenclature. This and the lack of knowledge concerning the synonomy of species has led to improper naming.

This was illustrated by a number of examples.

A new pathogenic fungus—the sporothrix of Schenck: PROFESSOR LUDWIG HEKTOEN. (Read by Dr. Jordan.)

Schenck has described a case of subcutaneous, refractory abscesses, caused by a fungus which Erwin F. Smith tentatively assigns to the genus *Sporotrichum.*

In the case of a boy, five years old, under the care of Dr. Perkins of Shenandoah, Sava., an identical fungus was found to produce similar, refractory lesions as those described by Schenck; the process started in an abrasion of the left index finger, caused by a blow with a hammer, and during the next two to three months over twenty-five abscesses appeared under the skin and forearm. Ultimately, recovery took place.

The fungus was obtained in pure culture on two different occasions. It grows well in ordinary media, forming in the older agar cultures brownish, wrinkled and folded layers. Gelatin is slowly liquefied. Ærobic. Thermal death point about 60° C. It has a separate branching mycelium; clusters of five or six spores appear around the ends of the branches and single spores develop along their sides. The spores are ovate or apiculate, from three to five mikrons in their longest diameter. Grams stain positive.

It produces chronic suppuration in the skin of mice and extensive ulcers; small, chronic abscesses may develop in the abdominal lymph glands after subcutaneous injection. In white rats intra-abdominal injection is followed by the development of numerous nodules enclosing small abscesses; the pus is thick and viscid, and contains oval and oblong gram-staining bodies in large numbers, but no thread. Pure cultures of the fungus are readily obtainable from lesions both in mice and rats.

Rabbits, guinea pigs, dogs and pigeons are immune. In guinea pigs and dogs, small subcutaneous abscesses sometimes form after injection under the skin.

The importance of bacterial tests in the sanitary supervision of milk supplies: MARSHALL O. LEIGHTON.

The investigations taken as a basis for this paper were made during the three years ending June, 1899, under the authority of the Board of Health of Montclair, N. J. Seventeen dairies were included in the report, the bacterial tests in each being confined to the determination of 'numbers per cubic centimeter.'

The average results for each dairy during the whole term divided themselves into three classes: First, those dairies having an average below 15,000; second, those between 40,000 and 70,000, and third, those above 180,000.

Comparing the foregoing results with the dairies themselves, as shown by stereopticon views of each, it was found that the dairies in class No. 1 were of the most improved type, in which the utmost cleanliness prevailed. Representing class No. 2, poorly equipped dairies were shown, in which the owners plainly endeavored to do their utmost with the crude means at hand to produce a pure product, but were unable to provide proper sanitary appliances to aid them; while class No. 3 represented those dairies in which neither good equipment nor good intentions prevailed, but in which ignorance and indifference combined to produce poor dairies and unwholesome supplies. The comparison between the results of the determinations and the sanitary condition of the dairies was plainly marked in the photographic plates thrown upon the screen.

The practical importance of such an investigation was demonstrated in the publication of each year's results in the annual reports. The public have given them serious consideration and, in consequence, no less than a dozen unworthy dairymen have found their business unprofitable. In addition to this, several dairies have undergone a complete change in construction and in methods of production, and the supply as a whole had been raised to a high standard of purity.

Notes on the effect of blood serum from tuberculous animals and men on the tubercle bacillus when mixed with it in the culture tube and hanging drop: Dr. W. H. Park.

The serum was obtained through blisters from twenty-four persons, twelve having tuberculosis, and twelve not having any sign of the disease. The tubercle bacilli from a recent culture were ground up and a fine watery emulsion made. To this emulsion, divided into separate tubes, was added the serum from the different cases, to an amount such that in each case a 10 per cent. solution of serum resulted. Although in some the film forming on the slanted tubes was more tenacious than in others, no difference on the whole was seen between the dilution of serum from tubercular cases and that from non-tubercular ones. The result on the whole did not seem to offer much practical help.

On the bacteriology of canned goods, with a detailed account of bacteria detected in sour corn: S. C. Prescott.

The paper described some investigations upon the bacteria present in preserved cans of corn which had become spoiled and 'swelled.' The cause of the trouble was found to be the presence of certain species of bacilli which resisted the temperature used in canning the corn. The same bacilli were found upon the fresh corn and husks.

Experimental and statistical studies on the influence of cold upon the bacillus of typhoid fever, and its distribution: W. T. Sedgwick and C. E. A. Winslow. (Read by Mr. Winslow.)

A review of the literature on the subject of ice-supply and the public health shows that, while pollution of ice-ponds appears to have caused intestinal disturbance, no epidemic of typhoid fever has been satisfactorily traced to such a source. While it is known that cultures of the typhoid fever germ are not sterilized, the important question of the quantitative reduction of this species by freezing has been studied in only two limited investigations. The authors have, therefore, frozen large numbers of tubes of water inoculated with four different races of the typhoid bacillus, and determined the reduction after various periods. The results, twenty tubes being averaged for each period, show a rapid reduction in the first hour in freezing, varying from 30 per cent. in one culture to 60 per cent. in another; the reduction then proceeds approximately with the time of freezing, reaching a constant value of over 99 per cent. in two weeks. The last two or three germs per thousand appear to be very resistant, some remaining after twelve weeks of freezing. The four races used show constant individual differences in their susceptibility to cold. Alternate freezing and thawing was tested and found only slightly more destructive than continuous freezing. The destruction of the germ in cool, but unfrozen water, followed the same laws, actual freezing causing only a slightly greater reduction than a temperature just above the freezing point. Finally, a few experiments on the formation of ice on a free surface showed that 90 per cent. of the germs present were excluded from the ice by physical processes. The authors conclude that the danger of typhoid infection from the small fraction of weakened germs remaining in natural ice is probably not a serious one, and that the results of their experiments are in harmony with the facts of experience.

Secretary.

SCIENTIFIC BOOKS.

Psychology and Life. By HUGO MÜNSTERBERG. Boston, Houghton, Mifflin & Co. Pp. xi+286.

Professor Münsterberg has here gathered together a number of essays, and has given to the collection the title of the first of the papers. The others are discussions of the relation of Psychology to Physiology, Education, Art, History and 'Psychical Research,' respectively. The chapters thus have a common starting point in Psychology from which they veer off in different directions. The author's special comments in these many fields it is impossible to reproduce here even in outline; we must confine ourselves to the more general doctrine presented in the work.

The book is in many ways an exposition, or at least the hint, of a philosophy; and to deal with it adequately would take one inevitably into deep water. With his main contention that Psychology is but a partial way of dealing with the mind, the present writer feels entire sympathy. It is important to have it put strongly by a psychologist that when we shall have catalogued all the facts of our mental life and have discovered their causal order—which is the purpose of psychology—there still remain the larger questions which have to do with the value and meaning of these occurrences. Psychology, like any natural science, is concerned merely with the facts; its aim is to describe and explain things; and to this end leaves out of account the all-important problem of what our consciousness signifies or what its ideals should be. The things we perceive, he is fond of saying, merely 'exist' but are not 'real'. For this reason the real mental life—the life of will, of action, of valuation, of ideals—lies outside the province of psychology, which is ever busy with the beggarly elements of the mental life and never takes up the problems that interest us as active and moral beings—questions of deeper truth, of beauty, of conscience and religion. The scientific spirit is consequently something which stands in contrast with real life; it is no substitute for the moral and religious spirit.

At the same time Professor Münsterberg somewhat clouds this correct perception of his by putting the antithesis between facts and values too strongly. At times it looks almost as if each could get along without the other; as if a great gulf were fixed between them, so that the realm of ideas appears in almost Platonic isolation from the world of sense-perception. The 'world of values' and the 'world of facts' are of course not two worlds, but rather different ways of considering the self-same world. In Kantian phrase, we might say that facts without values are blind, while values without facts are empty. Professor Münsterberg shows, at least in one passage, that he himself takes this view; but a certain love of contrast and antithesis, too often makes him put the matter otherwise.

And in his endeavor to show the insufficiency of the psychological standpoint, the author really does injustice to psychology. He holds that psychology does, and must 'transform' the facts for purposes of explanation; and explanation, he believes, is possible only when we can restate the facts in terms of atoms or something else equally elementary. In psychology, consequently, everything must, by hook or crook, be analyzed into *sensations*, since these are the mental elements which correspond to the atoms of the physical world. Even when we distinctly know that the real mental process —an idea, an emotion, or act of will—is *not* completely described when we have enumerated the sensations that compose it, nevertheless (according to the author) the psychologist is by the logic of the situation forced to shut his eyes to anything but these sensations and their laws. He must at least make believe that the act of will, for instance, is composed merely of sensations chiefly from the muscles, because only thereby is 'explanation' possible. In psychology, consequently, the truth is inevitably concealed, and some complex of sensations is substituted for the real mental process which we are to explain.

Few psychologists, I feel sure, would admit that this is a correct account of the psychological method. It sounds almost like a veiled *apologia* for some of the theories of both Professor Münsterberg and Professor James. They have each in their own way attempted to convince the world that certain 'complexes of sensations' were the whole truth in an act of will or an emotion; and the world has in the main steadily refused to be convinced. But now we are, as it were, called into the private office, and are told: "Of course, gentlemen, the complexes of sensations really are *not* the will or the emotion, but that is what we have to say they are if we are to be faithful to psychology."

But if in actually experiencing volition or emotion we clearly see that it is not a mere group of sensations, why should we be called upon gravely to declare in our psychologies the opposite? There is nothing in the rules of psychology to prevent our saying all the while that we are talking about the *sensations* characteristic of will or of emotion or of judgment—a mere part of the full process in consciousness. And if we can see, for instance, that a judgment has features additional to the mere sensations of muscular flexion or extension, I see no reason why, as psychologists, we should say, resignedly, that these other features are indescribable and beyond the pale of science. Quite apart from the question of values or of ideals, the experience itself reveals peculiarities of form that are quite definite and intelligible and communicable—has subject and predicate and the affirmative or negative connection, all of which are absent when the same sensations appear in a merely associative or temporal connection. Professor Münsterberg gives no sufficient reason why psychologists should hold that sensations are the only things in a mental process that are definite and describable and capable of helping to explain the process. As well might the physicist say that in his realm the bare atoms are all that he can take account of; when, in fact, time and distance are most necessary for any explanation that really explains. In other words, physical science has to take account both of the 'elements' and of their relationship or 'form.' And psychologists must do the same, noting not only such relations as are common to psychology and the physical sciences (time, for instance), but searching diligently whether there may not be some that are peculiar to our private mental life.

The general trend of the book, as can be readily seen, is to propose a more moderate estimate of psychology in general and of the laboratory work particularly. The later methods all come in for a drubbing: there is no quantitative work possible by psychological experiments; the brain physiologists can only borrow from psychology but give nothing in return; and child-study, with honorable exceptions, is something of a humbug. So that the general tone is a trifle disheartening to any of us who have faith in psychology and wish it well. As a counter-blast to those writings that magnify the office of psychology it may serve a good purpose. And since it is largely addressed to teachers, its chief benefit will undoubtedly be to remind them that a correct appreciation of the child and of the aims and ideals which are to be aroused in him is quite as important as a knowledge of the mechanism of the child's mind.

GEORGE M. STRATTON.

UNIVERSITY OF CALIFORNIA.

The Races of Man. An Outline of Anthropology and Ethnography. By J. DENIKER, SC. D. (Paris)–London. 1900. Walter Scott (American publishers, Charles Scribner's Sons). 611 pp., 176 illus., 2 maps.

The author of this handy text-book, forming Volume 37 in the Contemporary Science Series, is librarian of the Musée d'Histoire Naturelle in Paris. Moreover, he is a ripe specialist in human biology. Having, then, his own past experience as a guide, and being in touch with all the literature upon his theme, one is not surprised to find him interesting and instructive at every point. We may divide the volume into three parts:

Part I. Somatic characters, morphological and physiological, Chapters I.–III.

Part II. Ethnic characters, linguistic, industrial, sociological, Chapters IV.–VIII.

Part III. Classification of races and peoples, general and ethnic, IX. to close.

The first and the third parts are the best written, being in the author's special line. One is always eager to find out the point of view of a work like this, and we are not kept in suspense. 'Ethnic groups' are at once separated from 'somatological units' or 'races.' The latter are "theoretic types formed of an aggregation of physical characters combined in a certain way." These entities, theoretic conceptions, are exactly like species in zoology. Here is Deniker's list:

		RACES AND SUB-RACES.
A. WOOLLY HAIR, BROAD NOSE.		
	Yellow, short, dolicho.	1. *Bushmen* (s. r. Hottentots and Bushmen).
Dark skin.	Reddish-brown, short, sub-brachy, sub-dolicho.	2. *Negrito* (s. r. Negrillo and Negrito).
Dark skin.	Black, tall, dolicho.	3. *Negro* (s. r. Nigritian and Bantu).
Dark skin.	Brown, black, medium height, dolicho.	4. *Melanesian* (s. r. Papuan and Melanesian).
B. CURLY OR WAVY HAIR.		
Dark skin.	Reddish-brown, leptorhine, tall, dolicho.	5. *Ethiopian.*
Dark skin.	Chocolate, brown, platyrhine, medium dolicho.	6. *Australian.*
Dark skin.	Brownish-black, short, dolicho.	7. *Dravidian* (s. r. Platyrhine, leptorhine).
	Tawny white, leptorhine, brachy., nose hooked, etc.	8. *Assyrioid.*
C. WAVY, DARK HAIR, DARK EYES.		
	Brown skin, black hair, nose narrow, tall, dolicho., ellipitical face.	9. *Indo-Afghan.*
Tawny skin, black hair. Tall.	Aquiline nose, dolicho.	10. *Arab or Semite.*
Tawny skin, black hair. Tall.	Straight nose, dolicho., square face.	11. *Berber* (4 subraces).
Tawny skin, black hair. Tall.	Straight nose, meso-, oval face.	12. *Littoral European.*
Tawny skin, black hair.	Short, dolicho.	13. *Ibero-Insular.*
Dull white skin, brown hair.	Short, brachy, round face.	14. *Western European.*
D. FAIR, WAVY OR STRAIGHT HAIR, LIGHT EYES.		
Reddish white	Wavy, reddish, hair, tall, dolicho.	16. *Northern European.*
Reddish white	Flaxen hair, straightish; short, sub-brachy.	17. *Eastern European.*
E. STRAIGHT OR WAVY HAIR, DARK EYES.		
	Brown, hairy; broad concave nose, dolicho.	18. *Ainu.*
Yellow skin, smooth body.	Prominent nose, tall; elliptical face, brachy or meso.	19. *Polynesian.*
Yellow skin, smooth body.	Short, flat nose, high cheek bone, angular form, dolicho.	20. *Indonesian.*
Yellow skin, smooth body.	Short, prominent straight or concave nose; meso- or dolicho.	21. *South American* (s. r. Palaio-American, S. American).
F. STRAIGHT HAIR.		
Warm, yellow skin. nose straight or aquiline	Tall, Meso.	22. *North American* (s. r. Atlantic, Pacific).
Warm, yellow skin. nose straight or aquiline	Short, brachy.	23. *Central American.*
Warm, yellow skin.	Straight nose, tall, brachy, square face.	24. *Patagonian.*
	Brown-yellow, short, dolicho., round, flat face.	25. *Eskimo.*
Yellow-white skin.	Turned up nose, short, brachy.	26. *Lapp.*
Yellow-white skin.	Straight or concave, nose, short, meso-. or dolicho., high cheek bone.	27. *Ugrian* (s. r. Ugrian and Yeniseian).
Yellow-white skin.	Straight nose, medium height, hyper-brachy.	28. *Turkish or Turko-Tartar.*
	Pale yellow, high-cheek bone, Mongol eye, slightly brachy.	29. *Mongol* (s. r. Northern and Southern).

The succeeding table shows these races in their geographic contiguities.

The last chapters deal with the races by continents. Here the reader will find always references to the best special authorities where the author's statements are meagre. It is a pity that the Bureau of American Ethnology could not have read the proof of names for this continent. It is a little difficult for the English reader to detect 'Shahaptian' in 'Chahaptes.' The Trenton gravel controversy is an open question, and Dr. Deniker should have left it so on page 511. He does the cause no good, and his friends, Wilson and Boule, harm in setting them up as a court of last appeal.

O. T. Mason.

Malay Magic: Being an Introduction to the Folk and Popular Religion of the Malay Peninsula. By Walter William Skeat, with preface by Charles Otto Blagdon. London, Macmillan & Co. 1900. Pp. xiv + 686, 7 figs., 28 plates. Price, $6.50.

The folk mind, everywhere, stands in the same relation to truth that a celestial globe occupies with respect to the heavens. Here and there a star is in the right place, but all the rest is fanciful. But truth is exact agreement between what is and what is said, so, notwithstanding folk-lore is fancy, the beliefs are actually held, and we may have the truth about them. No other student within our acquaintance is better equipped for a work of this kind than Mr. Skeat.

Folk-lore, in this volume, is taken to mean the lore of the uncivilized races, containing in the germ, as yet undeveloped, the notions from which religion, law, medicine, philosophy, natural science and social customs are evolved. The operative side of living is excluded, but the regulative thoughts are folk-lore.

The word Malay incidentally includes with the people of that race in the peninsula others of the same blood near by, but the lore of the Chinese and other non-Malayan folk is excluded. The magician is the middle man between Malays and the spirit world. If he knows and reveals, he is *Pawang;* if he heals, he is *Bomor.* All that either does or says is classed by Mr. Skeats under magic. The Malays have had a series of religions, to wit, the aboriginal cult, which is a primitive sort of Brahmanism, with extensive pantheon, Buddhism and Mohammedanism. Now, it is easily comprehended, as Mr. Skeat shows, that these *Pawangs* and *Bomors* have nothing to do with *Imams, Khatibs* and *Bilals* of the mosques. Also, if the reader is familiar with the present cult of the Latin American tribes, or of the Filippinos, he would not be shocked to see a long string of Malay invocations and magical rites performed before Hindu divinities, demons, ghosts and nature spirits, beginning with: "*In the name of God, the Merciful, the Compassionate,*" and ending with: "*There is no god but God, and Mohammed is His prophet.*"

In order to prepare the way for a better comprehension of Malay magic the author devotes the first fifty pages to native cosmogony, anthropogony, animism and notions about souls. Nearly as many pages discuss the world of spirits, the Malay pantheon and its relation to our world, as well as the class of men who act as go between from world to world.

The remainder of the work gives us the story of Malay beliefs and practices concerning fire, air, earth, water, and the life of man, in which the spirit world is involved, together with the description of paraphernalia the recital of formulæ, prayers, sacrifices, lustrations, fastings, divinations and witchcraft involved. Wisely, in the midst of so much jumbling of ethnic creeds and cults, the author abstains from attempts to analyze, and contents himself with recording in the most scrupulous manner the data on which philosophic discussion must be based. Pages 581-672 are devoted to Malay texts.

It would be unkind to point out little errors and omissions, since an enforced absence from England prevented the author from revising the proofs. The illustrations are not so good as those of Dr. Fewkes along the same line published by the Smithsonian Institution.

O. T. Mason.

Plant Structures. A second book of Botany. By John M. Coulter, A.M., Ph.D., Head of Department of Botany, University of Chicago. Twentieth Century Text-Books. D. Appleton & Company. 1900. Pp. x + 348. 12mo, with 289 illustrations.

Several months ago the companion volume to the work now under review appeared, and was noticed in Science (December 8, 1899). That volume was designated as 'a first book of botany,' while this is said to be 'a second book.' The former ('Plant Relations') attempted to treat the subject from an ecological standpoint, and in our opinion the author failed to make it 'a first book'; in the present volume morphology is the dominant subject, and, as if in some doubt himself, the author says in the preface: "It may be, however, that many teachers will prefer to begin with the morphological standpoint as given in this book. Recognizing this fact 'Plant Structures' has been made an independent volume that may precede or follow the other, or may provide a brief course of botanical study in itself." This remarkably flexible purpose has been well carried out by the author. He has made an excellent *first* book of botany, in spite of its title.

The book follows the approved sequence from the simpler to the more complex plants, and the treatment is that which has been developed in the best botanical laboratories. The very helpful 'Suggestions to Teachers,' prepared by Dr. Caldwell to accompany the book, emphasize the practicability of the course here outlined. One feels as he runs over the pages that he is on ground which has been traversed again and again by teachers and pupils, and that all the work outlined *can* be done, because it *has been* done again and again.

We should like to take up the chapters in detail, but that cannot be done in a brief notice. We could ask here and there for a less confusing sequence (*e. g.*, where Slime Moulds and Bacteria are taken up after Toadstools and Puffballs, and Coleochæte in the midst of the Bryophytes), and far less of generalization before the pupil has some facts in hand (*e. g.*, in Chapter III., where the evolution of sex is discussed when he is as yet in total ignorance of the structural facts on which the theory is hung). On the other hand, the author's generalizations in the form of summaries from preceding groups (*e. g.*, Thallophytes, Bryophytes and Pteridophytes), are admirable.

The illustrations are good, and well chosen. Many have a delightful freshness, in sharp contrast to the well-worn cuts so long familiar in similar text-books.

CHARLES E. BESSEY.

THE UNIVERSITY OF NEBRASKA.

Observations made at the Blue Hill Meteorological Observatory, Massachusetts, U. S. A., in the Years 1897 and 1898. Under the direction of A. LAWRENCE ROTCH, A.M. With an Appendix containing the *International Cloud Measurements during 1896–97.* Annals of the Astronomical Observatory of Harvard College. Vol. XLII. Part II. 4to. Cambridge, 1900. Pp. 131–280.

The cloud work done at Blue Hill Observatory is known to meteorologists the world over, the publications on clouds already issued by this Observatory having been among the most important contributions to meteorology in recent years. This satisfactory result has been made possible through the liberality of Mr. A. Lawrence Rotch, the founder and director of the Observatory, and through the admirable work done at the Observatory by Mr. H. Helm Clayton and his associates, Messrs. S. P. Fergusson and A. E. Sweetland. Mr. Clayton's *Discussion of the Cloud Observations* made at Blue Hill (Annals Harv. Coll. Obs'y, Vol. XXX., Part IV.), is the most complete publication on clouds ever issued (see SCIENCE, N. S., Vol. V., 1897, pp. 468–469). When the 'International Cloud Year' was begun on May 1, 1896, in accordance with the recommendation of the International Meteorological Committee in 1894, the Blue Hill Observatory was one of the stations in the United States which co-operated in this special work, the other stations being those under the jurisdiction of the Weather Bureau. The present volume includes the usual meteorological observations made during 1897 and 1898, publication of which was delayed in order that an appendix containing a discussion, by Mr. H. H. Clayton, of the *Measurements of Cloud Heights, Velocities and Directions*, carried out during the 'Cloud Year,' might be included. In this Appendix are printed the tables containing details of all the cloud observations made throughout the 'Cloud Year,' together with tables showing the mean heights and mean velocities of the clouds at different hours and seasons; the number of clouds and measurements; the mean, maximum and minimum heights and velocities by months; the mean heights with different temperatures and pressures; the mean heights with different gradients; the mean heights of clouds from different directions; the mean velocities and frequencies of the clouds at different heights; the frequencies of the different currents at different heights, etc. The mere enumeration of the headings of these tables will suffice to show the thoroughness of the work discussed in this volume—a thoroughness which is characteristic of all of Mr. Clayton's cloud studies. The text accompanying the tables discusses the methods of measurement and of computation employed, and the meteorological results of the investigation. It is impossible to present any adequate summary of the important results reached by Mr. Clayton. Those who seek further information should turn to the volume itself, which is worthy of careful study. There is, however, one point which we would notice here. From a series of special measurements of cumulus and fracto-cumulus clouds, made with a view to determining the relation between the heights of these clouds as obtained by theodolites and from the dew-point, it appears that turreted cumulus clouds are most frequent at the coldest time of day, and not at the warmest, as is the case with ordinary cumulus. Thus, as Mr. Clayton points out, it seems that the diurnal period of the turreted cumulus is not determined by heating at the ground but by cooling at the surface of the cloud. The turreted cumulus probably forms only when the decrease of temperature from other causes approaches the adiabatic rate. It is thus an indication of thunderstorms, for a rapid vertical decrease of temperature in the upper air, when combined with a rapid decrease in the lower air caused by heating at the ground, favors the ascent of columns of air from the ground, to great heights and this is a condition favorable to thunderstorms.

The present volume is fully worthy to take its place in the line of Blue Hill Observatory publications as another important American contribution to meteorology.

SOCIETIES AND ACADEMIES.

THE PHILOSOPHICAL SOCIETY OF WASHINGTON.

AT the 514th meeting of the Society, held at the Cosmos Club on March 3d, Professor C. Abbe read an obituary notice of Professor H. A. Hazen. Dr. L. A. Bauer, then gave a detailed statement of the methods to be pursued in carrying out the magnetic survey of the United States by the Division of Terrestial Magnetism of the U. S. Coast and Geodetic Survey.

As an indication of the scope and character of the data to be derived from the detailed magnetic survey of the United States, a brief statement was given regarding the results obtained from the detailed magnetic surveys of Maryland and of North Carolina. Furthermore there were exhibited various charts giving a graphical analysis of the earth's magnetic field for various portions of the United States.

With the aid of these charts, it was shown very clearly how inadequate it is for the formation of theories of the earth's magnetism to have simply declination data alone.

Following Dr. Bauer's paper, Dr. Alexander Macfarlane of Lehigh University, discussed the 'Square Root of minus one.' He reviewed the explanations published by Payfair, Buée, Argaud, Français, Gauss, Cauchy, Boole, Hamilton, Cayley and other mathematicians and concluded that $\sqrt{-1}$ does not indicate direction nor rotation of the quantity to which it is attached, nor a turning of the plane of representation, nor a special unit; that + and — are not signs of addition and subtraction but are signs of affection, and so is $\sqrt{-1}$. He gave analytical expressions for these signs, which show their connection with π and applied them to explain the rule of signs, the roots of + and —, the logarithm of quantities, the fundamental rules of quaternions and vector-analysis, the analogy of the circle to the hyperbola, and imaginary intersections.

E. D. PRESTON,
Secretary.

THE TEXAS ACADEMY OF SCIENCE.

THE regular monthly meeting of the Texas Academy of Science was held in the Chemical lecture room of the University of Texas on Friday evening, February 16th, President Simonds in the chair.

Dr. H. Y. Benedict, Instructor in Mathematics and Astronomy in the University, spoke on 'Astronomy in the XIX. Century' which took the form of a summary of achievements in that branch of science during the past hundred years. First he considered the additions to instruments, the invention of which had materially assisted in the refinement and increase of our knowledge, special mention being made of the spectroscope, camera, photometer, etc.

Additions to the solar system constituted the next topic. These were both numerous and important, including one planet—Neptune—its satellite, the two satellites of Mars, the fifth of Jupiter, Hyperion and the ninth of Saturn, and the two of Uranus.

The cometary and periodic movements of meteorites were mentioned as were also the measurements of the parallaxes of the fixed stars.

The last topic, the 'Nebular Hypothesis and the Theory of Tidal Evolution,' aroused considerable enthusiasm. Among those who took part in the discussion were Professors Halsted, Harper, Ellis and Mezes. Throughout the paper it was made plain that in the astronomical work of the century Americans had played a leading part.

Dr. L. E. Dickson, Associate Professor of Mathematics, presented a paper entitled 'An Elementary Account of the Greater Problems solved by the Modern Group Theory.' Among the examples chosen to illustrate the definition of a group, the most elementary was that of the three distinct rotations of a plane triangle into itself, viz, the right-hand and the left-hand rotations through 120° and the zero-rotation called the identity. Denoting them by R, L, I, respectively, it is seen by inspection that

$$R^2 = L, \quad L^2 = R, \quad RL = LR = R^3 = L^3 = I,$$

so that the result of applying any one of the three and afterwards any one of the three is equivalent to applying some single one of the three. The corresponding permutations of the three vertices give rise to a 'group of substitutions.'

The connection between rational, integral functions and groups of substitutions was illustrated by several examples. The solution of the quadratic and cubic equations was made to depend upon the determination of very simple non-symmetric functions of their roots. After indicating the impossibility of solving by radicals the general equation of degree $n > 4$, the question of the solution of special equations was declared to be a problem capable of most direct answer by employing the group of the equation, as developed by Galois. A problem in mathematics usually depends upon the solution of an algebraic equation or upon the integration of a differential equation. By considering the group of the equation, finite in the former case and continuous in the latter, we are able to decide whether or not the equation can be solved by radicals or integrated by quadratures. More generally it tells what series of simple problems may be taken in place of the original problem. The group of a problem not capable of such a reduction to a chain of simpler problems is called simple. To borrow a chemical term, these simple groups are the 'elements,' to which any problem in its final analysis is to be reduced. The present state of our knowledge of these elements was discussed both for finite groups and for continuous groups.

Professor Thos. U. Taylor, M.C.E., read an abstract of his report to the U. S. Geological Survey on 'The Silting up of Lake McDonald, Austin, Texas.' This is the body of water retarded by the erection of the great dam across the Colorado River. A comparison of the cross-sections of the lake at sixteen different stations, averaging $1\frac{1}{4}$ miles apart, for 1893 and 1900, shows that the lake had silted up 48 per cent. of its original storage capacity; that when reduced to a square mile base there was in 1893 a storage capacity of 81 feet in depth, but in 1900 only 42 feet. This result, reached in the space of 6⅞ years, gives an average of 5.8 feet of silt per year on the mile base. According to the laws of silting the deposit was for the first year 7.5 feet, for the second year 6.9 feet, for the third year 6.2 feet, etc. The silt in the upper two miles of the lake is mostly sand, while that of the lower two-thirds is composed of a fine, impalpable, absolutely gritless deposit. The Colorado River flows through a hilly country for hundreds of miles, and is not a heavy silt-bearing stream except on the Red Fork.

F. W. S.

University of Texas.

THE ACADEMY OF SCIENCE OF ST. LOUIS.

At the meeting of the Academy of Science of St. Louis of March 5, 1900, forty-two persons present, the following subjects were presented:

'An Annotated Catalogue of the Muricidae,' by Mr. F. C. Baker, was presented by title.

A paper by Professor A. S. Hitchcock, entitled 'Studies on Subterranean Organs.' II. 'Some Dicotyledonous Herbaceous Plants of Manhattan, Kansas,' was presented in abstract and illustrated by specimens.

Mr. J. S. Thurman addressed the Academy on 'Liquid Air,' tracing the history of the liquefaction of gases and in particular the success reached in liquefying air since this result was first achieved in 1877 by Pictet and Cailletet. The possibilities of the utilization of liquid air as a motive power and an explosive, and its employment in medicine and as a disinfectant, were passed in analytic review by the speaker, whose conclusions were that there seemed no present probability of its useful application either as a disinfectant or a motive power. In medicine and for certain purposes requiring the use of explosives it was stated to be not impossible that it would ultimately find useful application, although its prospects as an explosive did not seem very promising.

Four persons were elected active members of the Academy.

William Trelease,
Recording Secretary.

ANTI-PLAGUE INOCULATION.

The Indian Plague Commission have made public through the India office part of their report, including the following paragraphs in regard to anti-plague inoculation:

With regard to the feasibility of adopting a general policy of inoculation, our conclusion may be set forth as follows:

(1) Experience gained hitherto has shown that it is very seldom possible to get a large proportion of the inhabitants of an uninfected place inoculated.

(2) It has been possible, where the inducement of exemption from segregation and eviction has been offered, to get a large proportion of the inhabitants of an infected place inoculated quickly.

(3) It has been possible in one place—Mysore City—even where no inducement that touched the great mass of the people could be offered, to get a considerable proportion of the inhabitants of an infected place inoculated quickly.

(4) It has been possible also to induce a large proportion of particular communities, such as the Khojas of Bombay and Karachi, to be inoculated under the influence of their leaders.

Our recommendations are governed by those conclusions, as well as by the conclusions we have already drawn with regard to the protection conferred by inoculation. They are further governed by the consideration that it is necessary, as far as may be possible, to dispel the particular objections on account of which the people have hitherto refrained from inoculation. Moreover, our recommendations are based on the consideration that it is advisable to make the operation as effective as possible, as little inconvenient as possible to the person inoculated, and as easily carried out as possible by the inoculator.

I. We have already insisted on the necessity for the accurate standardization of the vaccine, as being essential to the attainment of the best results, both as to the protection conferred and as to the duration of that protection. We have pointed out, also, that the introduction of an accurate system of standardization may possibly obviate the necessity of employing two successive inoculations.

II. With a view to dispelling the natural fears of the people and avoiding all unnecessary risk to the inoculated, and, further, with a view to enabling the inoculations to be carried on with the least possible amount of attendant inconvenience, we would insist upon the necessity that stringent precautions should be taken to insure that all the vaccine used is quite free from contamination, and we would recommend that the volume of the necessary dose should be made as small as possible.

III. With a view to removing any possible ground for distrust as to the conveyance of disease by inoculation from one person to another we would recommend that the syringe should be sterilized in the presence of the person about to be inoculated.

IV. We are of the opinion that inoculations, under the safeguards and conditions stated above, should be encouraged wherever possible, and, in particular, it seems to us desirable to encourage inoculation among disinfecting staffs and the attendants of plague hospitals.

We cannot bring to a conclusion this consideration of anti-plague inoculation by Mr. Haffkine's prophylactic fluid without expressing our sense of the importance of the method which Mr. Haffkine has devised and of the results which have been achieved by it. The credit due to Mr. Haffkine is the greater because the difficulties with which he had to contend in this matter could only have been overcome by great zeal and endurance. Mr. Haffkine's work on anti-plague inoculation, while not based on any new scientific principle, constitutes, it seems to us, a great practical achievement in the region of preventive medicine.

SPIRIT-LORE OF THE MICRONESIANS.

RECENTLY the director of the ethnographic division of the royal museums at Berlin has returned from a prolonged visit to the Sunda islands, Micronesia and Melanesia, and is now able to give to the world the multifarious results of his observations and researches. Micronesia had heretofore been studied in part only, as far as its ethnography is concerned, and it was chiefly the Pelew islands that had attracted a share of attention from German scientists; although the Mariana islands had been considered also. Research has now been made much easier by the number of colonies which Germany has established in this insular domain.

The entire group of the Carolinian islands, with a native population of about 30,000, is what Director Adolph Bastian chiefly describes in his recent publication, 'Die mikronesischen Colonien aus ethnologischen Gesichtspüncten,' Berlin, 1899. Octavo, pp. 7 and 370. To begin with, Dr. Bastian gives a sketch of the social life of the Pelew nation, of their chiefs, notables and government. Then follow his observations on mortuary rites, their theories about death, the soul after death and the mutual intercourse of souls. Then are discussed Malay theories of black and white magic (whatsoever this may be), of demonology, the tutelary genii, the creation of the world, evolution and what we call the infinite. The demonology is among the Malays weird and fantastic, as might be expected, but also highly poetical and full of originality. For many years back the white race has been informed of the religious views and mythology of the Maori, the Samoa, Tonga and Mangaia islanders, and there is no denial of the fact that the cosmogony and spirit-worlds of these natives are as grand in their conception as those of many peoples of European antiquity. Their systems of the world and of after-life come very near the metaphysical, and when the European who transmits these views to us is himself a philosopher, or at least a thinker, he will make the Malay systems appear to us so much the more philosophical. Dr. Bastian, being a votary of the comparative method in ethnology, has for every myth, custom or belief a score of parallels ready, which he takes from Mediterranean, African, American or any other tribes or nations of the globe, or historic comparisons of beliefs from Greece, Rome, Mesopotamia, China, or Mexico. Anyone able to follow Bastian in his vast amount of reading (his quotations of sources are *summary* and therefore of little use), will undoubtedly derive benefit from what he states. But these statements are given in a manner that is too chaotic and profuse and most readers find it too difficult to follow the thread of his argumentation.

Oracles through whistling are found throughout these islands. Their main gods transmit their behests to men through ghosts or dead children by whistling sounds or whispered words. Tattooing is permitted only when a deity has given his assent by whistling; house spirits and the genii of trees give their revelations by whispers only. A. S. G.

APPLIED THERMODYNAMICS.

IN a recent publication of '*Documents sur la Laboratoire de Mécanique de l' Université de Liége,*' describing its methods of instruction, by the Professor of Applied Mechanics and of Industrial Physics, M. Dwelshauvers-Dery, we find a *resumé* of researches in applied thermodynamics, mainly in the experimental study of the steam-engine, which is interesting as exhibiting the character and extent of the work recently performed, and valuable as supplying important data previously unknown.

This laboratory of applied mechanics was completed in 1893, after, as the author of these documents says, five years of constant solicitation of the government to supply this '*auxiliaire précieux,*' of which M. Dwelshauvers-Dery was the first to conceive the idea, a generation ago, though so late in its realization. His idea was that of a laboratory of research and instruction in engineering, to be employed in the work of the regular courses leading to technical degrees and devoted to the purposes of the student, rather than, as previously usual in nearly all departments of applied science, primarily for those of the distinguished professor in charge and only secondarily and incidentally for the student.

The researches which have been conducted since the date of completion of this laboratory by the Director, assisted by his staff and by advanced and able students, have been mainly in applied thermodynamics. M. Dwelshauvers-Dery is a disciple of Hirn and aided in the investigations made in Alsace at the beginning of the work of his eminent leader. Since that time, the famous discussion between Zeuner and Hirn and their followers has made this work and these workers familiar to all investigators and students in that field. It has been in the supplementing of Hirn's earlier work that the experimental steam-'plant' at Liége has been mainly occupied recently.

Among other investigations, those relating to the influence of the water collecting in the steam-chest of the engine upon its efficiency, on the effect of superheating, on the use of the steam-jacket, on the effect in the real engine of compression, and those on the condition of the vapor, as to 'quality,' in the clearance spaces, have been the most extensive and important.

It was found to be the unquestionable fact that, with the engine employed, it was advantageous to continually drain the water of condensation from the valve-chest of the engine when using moist steam and whether the jacket is in use or not. With superheated steam, naturally, no effect was observed.

The steam-jacket was found to give an economy of from 24 to 28 per cent., either with or without superheating; the latter being a disputed question until thus, for this case, at least, settled. Superheating produced an economy of about 20 per cent., as a maximum.

The investigations of the quality of the vapor in the compression period occupied several years and attracted much attention and some opposition to the conclusions reached was manifested by a number of distinguished experts in that department. Those experiments which were made with 'constant absolute work' showed a decided loss by compression and a loss proportional to the amount of the compression; which fact was attributed to the heat-exchanges between vapor and cylinder-wall. This conclusion was challenged and it was denied that the fundamental assumption that, as asserted by Hirn, the steam at the end of emission is dry, could be accepted as true. Dwelshauvers-Dery and his former assistant and pupil, Duchesne, furnished proof of the correctness of his proposition. (Revue de Mécanique, Jan., 1899; July, 1899.)

Mr. Isherwood, the famous pioneer in this class of work and the Engineer-in-chief of the navy during our civil war, suggested that the experiments be repeated, making the 'indicated work' a constant quantity. He thought it possible that it might be found that the use of compression was neither economical nor wasteful in the actual case and, therefore, its use simply a question of smoothness of operation of the machine and entirely outside the realm of applied thermodynamics. The work of the past year has been in this line of investigation and the results have sustained the view of Commodore Isherwood.

The schedule of proposed work for the year 1900 includes the study of the effect of 'throttling' steam, as proposed by Isherwood.

The publication of these documents for the use of the Congress of Applied Mechanics at the coming International Exposition at Paris gives all interested in this department of research and in this kind of instruction an opportunity to learn just what are the methods employed, the apparatus used and the character of the researches best adapted for laboratory work of this sort in the instruction of the young engineer and physicist, as arranged by a pioneer in this field.* The work reported has been extensive, important and admirable in method and in its execution. It has been conducted under circumstances of very great difficulty, patiently, carefully, persistently, and while few who have not kept in touch with it while in progress can realize what labor and sacrifice have been involved, every specialist in this department will recognize its value and elegance.

R. H. THURSTON.

* Documents sur le Laboratoire de Mécanique de l'Université de Liége, et sur l'Enseignement qui y est donné par V. Dwelshauvers-Dery, Professeur de mécanique appliquée et de physique industrielle. Liége, Charles Desocr, Editeur, 1900.

A NEGLECTED DEPARTMENT.

THE American Society of Mechanical Engineers is issuing to its members a circular, prepared by its Council, calling attention to the neglect of the Patent Office of the United States by Congress, to its importance to the country and to its hoppled condition as produced by the refusal of Congress to provide for either suitable accommodations or a sufficient clerical force and staff of examiners. Members of the Society are urged to force upon the attention of their members of Congress the necessity of "providing sufficient room, force and facilities for the prompt and proper execution of its work," that arrangements be made at once for "providing incombustible receptacles for the records," which records "largely constitute the legal evidence of title of so many of the larger industries of the country," that the library be kept up and properly cared for, that the Patent Office be given the entire control and use of its own building—now occupied largely by 'squatters' from other bureaux—and that its earnings be dedicated to its own purposes and improvement. The Patent Office is 'out of practical politics,' and is only prevented from doing its full duty to the country by its lack of space and of force. Yet, up to January 1, 1899, 693,979 patents had been granted, and 41,422 trade-marks registered. Last year alone 25,527 patents and 2260 trade-marks were added to the record. The accumulations of records and of exhibits has come to be so great as to put it quite beyond the power of the restricted force in its restricted space to properly store, arrange, classify and care for them. The library, which it is imperatively necessary to keep up to the highest state of efficiency, and which should be a complete collection of the technical publications of the world, and of all time, was last year only allowed $1500 for purchases of books. No funds at all were obtainable for the law library. The whole business of this department of government, upon which the success of our great industries is so absolutely dependent is trammelled, and every industry of the country is embarrassed, by its forced inefficiency. This inefficiency is entirely due to the indifference of Congress. The Patent Office has accumulated out of its own earnings a large amount of available capital—several millions of dollars—and it has not been even allowed to draw upon its own funds to meet imperative needs.

So indifferent, in fact, have been some Congresses that it is within the experience of the writer that important matters of business, involving large interests, have been delayed for weeks through the impracticability of securing a full meeting of a committee, repeatedly called.

R. H. THURSTON.

MUSEUM OF THE STATE OF NEW YORK.

DURING the winter season, the energy of the museum staff has been concentrated on an important series of publications. A bulletin on the clay industries of the State will soon be issued, being a second edition of one prepared in 1893. A report on the lime and cement of the State is nearly ready for the printer. Work is also rapidly progressing on the new edition of the geologic map of the State on the scale of five miles to the inch.

A new edition of the Economic and Geologic map published in 1894 is almost ready for the engraver. It is on a slightly enlarged scale and will contain a large amount of additional information. A relief model of Niagara River and the vicinity of the Falls on the scale of 1000 feet to the inch is being prepared by Mr. Edwin E. Howell, of Washington, D. C., for exhibition at the Pan-American exposition in Buffalo.

The sixteenth annual report of the State geologist being the report of work done during the incumbency of the late Professor James Hall, has been issued. It contains a number of papers of importance, among them,

'Report on the boundary between the Potsdam and Pre-Cambrian rocks north of the Adirondacks,' by H. P. Cushing.

'The Naples fauna in western New York,' by John M. Clarke.

'The brine springs and salt wells in the State of New York and the geology of the salt district,' by D. D. Luther.

'The faunas of the Hamilton group of Eighteen-mile creek and vicinity,' by A. W. Grabau.

The department has received from Professor C. E. Beecher, of Yale University, a natural size restoration of the immense crablike crustacean *Stylonurus excelsior*, the largest invertebrate animal that has been found in the rocks of New York. It attained a length of about five feet, and its remains were found in the Catskill rocks of Delaware county.

Dr. J. M. Clarke lectured on the 24th ult. in the Columbia University series on the 'Geological History of Parasitism' and will repeat the lecture before the Rochester Academy of Science.

A bulletin on early and recent sites of the Indian tribes of the State, illustrated by two maps, will soon be received from the printer.

In zoology, the biological survey has been continued and volunteers have been organized to observe and report on the birds of New York. This is in continuance of the biological work originally begun under the natural history survey which led to the publication of the reports on zoology and botany in 1824, and which, though for some time suspended for lack of funds, was revived two years ago in the study and collection of fishes of Long Island by Dr. Tarleton H. Bean, and the preparation of a bulletin on the Mammals of New York, together with a key to their identification, now in press.

CURRENT NOTES ON METEOROLOGY.

THE RELATIVE HUMIDITY OF OUR HOUSES IN WINTER.

'The Relative Humidity of our Houses in Winter' is the subject of a paper by R. De C. Ward in the *Boston Medical and Surgical Journal* for March 1st. Observations were made by means of an ordinary sling psychrometer in a furnace-heated room during three weeks of last November. The mean relative humidity in the room for the whole period was 30%, while the mean relative humidity outdoors during the same period was 71%. The minimum relative humidity observed for any whole day was 24% and the maximum for a whole day was 40%. For purposes of comparison, the relative humidities of several stations in arid regions are given in the paper. For instance, the lowest mean annual relative humidity in the United States is that for Yuma, Ariz., which has 42.9%, and a mean monthly minimum of 34.7% in June. Sante Fé, N. Mex., has a mean annual of 44.8%, with a mean monthly minimum of 28.7% in June. Death Valley, Calif., was found to have a mean relative humidity of 23% during five months (May–September) of the year 1891, when a temporary meteorological station was maintained there by the Weather Bureau. Southwestern Siberia and Western Turkestan have a mean of 45–50% in July. Ghadames, in Tripoli, has 27% in July. In India, Lahore has 31% and Agra 36% in May. It thus appears that the air of the room in which the observations were made was drier than that of many desert regions.

DRUNKENNESS AND THE WEATHER.

Science for August 11th last contained an interesting paper by Dr. E. G. Dexter, entitled 'The Mental Effects of the Weather' in which the relations between certain weather elements and the occurrence of certain misdemeanors in New York City were discussed. In *Nature* for February 15th, Dr. Dexter returns to this subject in a communication which is supplementary to the article just referred to. In this note the writer refers to the results of a study made by him to determine the relation between temperature conditions and drunkenness in New York City. The number of arrests (males) for drunkenness for each day during the three years, 1893–1895, was taken from the records of the New York police force. The mean temperature, pressure, humidity and wind movement for each of these days were obtained from the records of the Weather Bureau in New York City. The curve showing the number of arrests for drunkenness plotted with reference to the twelve months of the year shows that the prevalence of intoxication during the cold months is much in excess of that for the warm ones. The curve of arrests for drunkenness plotted with reference to mean temperatures also shows, as a whole, a decrease in the number of cases of intoxication with increasing temperature.

INTERNATIONAL METEOROLOGICAL CONGRESS.

AN International Congress of Meteorology is to be held at Paris from September 10th to 16th of the present year. The President of the *Commission d'Organisation* of the Congress is M. Mascart, Director of the Central Meteorological Bureau of France. The Secretary is M. Angot. Membership in the Congress may be had on payment of 20 francs. The preliminary program includes a long list of subjects in meteorology proper, as well as in oceanography, and terrestrial magnetism and electricity.

RETIREMENT OF MR. R. H. SCOTT.

IT has already been announced in this JOURNAL that Mr. R. H. Scott, F.R.S., was to retire from the post of Secretary to the Meteorological Council of the Royal Society on February 28th. At the end of the year 1899, Mr. Scott had completed 33 years of service in the Meteorological Office, and for the last 25 years he has acted as Secretary of the International Meteorological Committee. Mr. Scott is to be succeeded by Mr. W. N. Shaw, P.R.S., Fellow of Emmanuel College, Cambridge, and up to this time Assistant Director of the Cavendish Laboratory, and Lecturer in Physics in the University of Cambridge.

R. DEC. WARD.

HARVARD UNIVERSITY.

SCIENTIFIC NOTES AND NEWS.

PROFESSOR P. TACCHINI has resigned the directorship of the Royal Italian Bureau of Meteorology and Geodesy after forty years of service. Professor Luigi Palazzo has been appointed temporary director.

THE Royal Academy of Turin has elected Dr. Charles S. Minot a corresponding member.

PROFESSOR MITAG-LEFFLER of Stockholm, has been elected a corresponding member of the Paris Academy of Sciences in the Section of geometry.

GLASGOW UNIVERSITY has offered the degree of LL.D., *honoris causa*, to Mr. A. Smith Woodward, the vertebrate paleontologist of the British Museum.

THE University of Aberdeen will confer the degree of LL.D. on Mr. W. R. Sorley, professor of moral philosophy in the University of Aberdeen.

MR. DEAN C. WORCESTER, whose appointment as a member of the new Philippine Commission we announced last week, has resigned the assistant professorship of zoology in the University of Michigan. It is reported that Mr. Worcester has been offered a salary of $15,000 a year as manager of certain mining interests in the Philippine Islands and that when his duties as commissioner are fulfilled he may accept the offer. His salary at the University of Michigan was $1600.

PROFESSOR PERRY G. HOLDEN has resigned the chair of agriculture in the University of Illinois to become manager of the agricultural department of the Illinois Sugar Refining Company.

Mr. W. A. Taylor, assistant chief of the division of pomology, department of agriculture, has sailed from New York to take charge of the United States exhibit of fruits at the Paris Exposition.

THE Rumford medal, which, as we announced sometime since, was awarded by the American Academy of Arts and Sciences to Mr. Charles F. Brush, was presented to him at a meeting held last week in Boston. Professor Charles R. Cross, of the Massachusetts Institute of Technology, Chairman of the Rumford Committee, made a brief address, describing the grounds for the award and the arc lamp invented by Mr. Brush; Professor Trowbridge presented the medal and Mr. Brush made a reply. Professor Elihu Thomson read a paper describing a new method of producing an electric current of high voltage.

COLUMBIA UNIVERSITY has been given a statuette of Professor Charles Hackley, who held the chair of mathematics and astronomy in Columbia College from 1843–1861.

WE regret to record the death at her home in New York city, of Miss Catherine Wolfe Bruce, who made generous gifts for the advancement of astronomy to Harvard University, Columbia University and other institutions.

M. EMMANUEL LIAIS, Mayor of Cherbourg, has died at the age of seventy-four. For many years he held posts at the Paris Observatory, and he was sent in 1857 to South America to watch the solar eclipse. He organized telegraphic meteorology in France, and devised the use of chronographs in determining longitude by electricity. He bequeaths his property to the municipality of Cherbourg in trust for scientific purposes.

DR. WILLIAM MARCET, F.R.S., died at Luxor, Egypt, on March 4th, in his seventy-second year. He had been president of the Royal Meteorological Society, and was the author of books on health resorts and on the history of the respiration of man.

DR. F. JAGOR, known for his scientific expeditions, died at Berlin on February 11th, at the age of 83 years.

DR. CARL MARIA PAUL, geologist of the Austrian bureau, died at Vienna on February 10th.

MR. JAMES G. SMITH, one of the inventors of the duplex system of telegraphy, died in New York City, on March 13th.

THE Fish Commission steamer *Albatross* has arrived at Yokohama. After refitting, the vessel will proceed to Alaska for the purpose of continuing the investigations in the salmon streams begun some years ago.

AN expedition consisting of Professor E. B. Poulton and Mr. E. S. Goodrich, from Oxford University, and Messrs Oldfield Thomas and R. I. Pocock, from the British Museum, is just starting for the Balearic Isles to make zoological collections. Although within easy reach, these islands are still little known to naturalists, so that the collections, if containing no novelties, will be of much service in completing the faunal series of the London and Oxford Museums.

MRS. PHOEBE HEARST has undertaken to defray the expenses of explorations and excavations in various parts of the world, to secure collections for the archæological museum to be established at the University of California. Dr. George A. Resinel is expected to have charge of the work in Egypt; Dr. Alfred Emerson in Greece and in Etruria; Dr. Euler in South America and Yucatan, and Dr. P. M. Jones in California and Mexico.

DR. J. W. GREGORY, the new professor of geology at Melbourne, has been appointed director of the scientific staff on the British Antarctic Expedition, which, as at present arranged, is to start in August, 1901. It is to be hoped that Dr. Gregory's recent severance from the British Museum will not prevent the natural history collections coming to that establishment as was originally intended. Another scientific man who thinks of taking a trip to the Antarctic is Dr. Otto Nordenskiöld.

THERE will be a Civil Service Examination, on April 17th, to fill the position of Field Assistant in the Division of Forestry, Department of Agriculture, at a salary of $1000 per annum.

BELGIUM has established a botanical garden and experiment station at Coquilhatville in the Congo Free State.

A BRANCH of the American Chemical Society has been established for the State of Michigan, with its headquarters at the University of Michigan. The first officers are: *Presiding Officer*, Professor A. B. Prescott; *Secretary*, Alfred H. White; *Councillor*, Professor Paul C. Freer—all of the University of Michigan. The members of the executive committee are: A. F. Shattuck, chemist to the Solvay Process Company, Detroit; Professor F. S. Kedzie of the Agricultural College, and J. V. Wolfe, Jr., chemist to the Detroit Sugar Company at Rochester.

THE New York *Evening Post* reports that a contract to slaughter 20,000 birds of all sorts near Milford, Delaware, for the benefit of a millinery firm in New York, has aroused a storm of indignation. Fully a dozen societies, headed by the Academy of Natural Science have taken action to prevent the killing of the birds. A notice denouncing the proposed slaughter has been sent out by Mr. Witmer Stone, Chairman of the American Ornithologists' Commmittee on Bird Protection. The committee will prosecute wherever the law is violated.

THE *Scientific American* states that the Geographical Society of Philadelphia is to continue its work of setting wooden casks adrift on the ice north of this continent, to demonstrate the currents of Arctic waters north of Behring Strait. Each cask will contain a blank to be filled in by the finder.

READERS of this JOURNAL have doubtless noticed in the daily papers the announcement of the excommunication of Dr. George St. Mivart from the Roman Catholic Church, because he would not revoke articles contributed by him to the *Fortnightly Review* and the *Nineteenth Century*. The formula sent by Cardinal Vaughan to Dr. Mivart for his signature has been published in the London *Times* and is herewith in part reproduced as an explicit statement of what must be believed by communicants in the Roman Catholic Church:

I therefore firmly believe and profess that the Blessed Virgin Mary conceived and brought forth the Son of God in an ineffable manner by the operation of the Holy Ghost, and absolutely without loss or detriment to her Virginity, and that she is really and in truth, as the Catholic Church most rightly calls her, the 'Ever Virgin'; that is to say, Virgin before the birth of Christ, Virgin in that birth, and Virgin after it, her sacred and spotless Virginity being perpetually preserved from the beginning, then, and for ever afterwards. * * * I firmly believe and profess in accordance with the Holy Council of Trent that the first man Adam, when he transgressed the command of God in Paradise, immediately lost the holiness and justice in which he had been constituted, and that he incurred through that prevarication the wrath and indignation of God, and that this prevarication of Adam injured, not himself alone, but his posterity, and that by it the holiness and justice received from God were lost by him, not for himself alone, but for us all. * * * I reject as false and heretical the assertion that it is possible at some time, according to the progress of science, to give to doctrines propounded by the Church a sense different from that which the Church has understood and understands, and consequently that the sense and meaning of her doctrines can ever be in the course of time practically explained away or reversed.

WE learn from *Nature* that the Reale Institute Lombardo has awarded its prizes as follows: The 'ordinary' prize offered by the Institution for the best catalogue of remarkable meteorological phenomena prior to 1800 was unawarded, but premiums of 400 lire have been awarded to three of the competitors, and the judges consider that the publication of the results arrived at conjointly by the three would be of great value. Under the Cagnola foundation five prizes were offered, and none awarded, the only award being a premium of 1000 lire to the sole competitor who sent in an essay on illustrations of Hertz's phenomena. On two of the other subjects no essays were sent in, and on the other two the essays were not of sufficient merit to justify an award. The Pizzamiglio prize and the Ciani prize, for essays in political science, and the Zanetti prize, for discoveries in pharmaceutical chemistry, are all unawarded. The Fossati prize, for an essay illustrative of the macro- and micro-scopic anatomy of the central nervous system, has been conferred on Dr. Emilio Veratti. In striking contrast to the paucity of competitors in subjects of a more or less academical character is the keen competition for the Brambilla prize, given "to one who has invented or introduced into Lombardy some machine or some industrial process from which the population may derive a real and proved benefit." Seventeen competitors entered for this prize, the awards including a gold medal and 500 lire each to Bianchi and Dubini, for desiccators of silk-cocoons; to

Aurelio Masera, for new processes connected with the textile industry; and to M. Rusconi, for developing the 'Mercer' process in the cotton industry. In addition, gold medals and 400 lire are awarded to Carlo Carloni, for his invention of a mastic called magnesite, as a substitute for red lead for junctions of pipes, also for a bicycle brake; to Demetrio Prada and Co., for extracts used in tanning and for the manufacture of oxygenated water; and to J. Löffler, for introducing into Milan the manufacture of artificial flowers in porcelain. A gold medal and 300 lire is awarded to the Italian Color Manufactory under Max Meyer & Co., and a bonus of 300 lire to E. Tuffanelli, of Milan, for an invention connected with water and gas pipes.

At the Royal Institution on March 2d, Major Ronald Ross delivered a lecture on 'Malaria and Mosquitoes.' According to the London *Times*, he first alluded to the discovery of the parasite of malaria by Laveran in 1880, and the failure of the subsequent attempts to find the parasites in the water and soil of malarious places. He described the theories of King, Laveran, Manson and Bignami that mosquitoes conveyed the disease, and said that it was Manson's theory alone which led to the solution of the problem. Believing that it was the only one of practical value, he undertook to verify Manson's theory, and began work in India in 1895. The task presented many difficulties, but after two and a-half years of failure he at last found the parasites growing in mosquitoes belonging to the genus called *Anopheles*. That was in August, 1897. The following year he completely traced the development of the malaria parasite of birds in the mosquito, and finally, in June, 1898, he succeeded in infecting a number of healthy birds with malaria by the bites of mosquitoes. His investigations had proved that not only the infection itself but the severity of it could be transmitted through the mosquito. Out of 28 healthy sparrows which were used, he succeeded in infecting 22, although he failed to transmit the infection from sparrows to several other kinds of birds. In December, 1898, his investigations were repeated and confirmed by Professor Koch and Professor Grassi, and Drs. Bignami and Bastianelli, who also succeeded in infecting healthy men by the bites of mosquitoes in Italy. The investigations had undergone great development since then. The mosquito theory explained all the facts about malaria.

UNIVERSITY AND EDUCATIONAL NEWS.

AN ASSOCIATION OF AMERICAN UNIVERSITIES.

The Chicago *University Record* gives an account of the meeting of representatives of certain institutions held at the University of Chicago, February 27th and 28th. The invitation to this meeting was made by the Presidents of Harvard University, Columbia University, Johns Hopkins University, the University of Chicago, and the University of California. There were present representatives of the University of California, the Catholic University of America, the University of Chicago, Clark University, Columbia University, Harvard University, Johns Hopkins University, Leland Stanford Jr. University, the University of Michigan, the University of Pennsylvania, Princeton University, the Federation of Graduate Clubs, and the United States Commissioner of Education.

After a full discussion, it was unanimously voted that the universities represented in the conference organize themselves into an association. A committee was appointed, consisting of President Jordan, President Harper, Professor Pettie, President Conaty, and Professor Newbold, to prepare the constitution of the association. At an adjourned meeting the following articles were adopted:

CONSTITUTION.

This organization is called the Association of American Universities.

It is founded for the purpose of considering matters of common interest relating to graduate study.

It is composed of institutions on the North American Continent engaged in giving advanced or graduate instruction.

Its initial membership consists of the following institutions:

University of California.	Clark University.
University of Chicago.	Cornell University.
Columbia University.	Johns Hopkins University.
Harvard University.	
University of Michigan.	Princeton University.

University of Pennsylvania.	Leland Stanford Jr. University.
University of Wisconsin.	Yale University.
Catholic University of America.	

Other institutions may be admitted, at the annual conference, on the invitation of the Executive Committee, endorsed by a three-fourths vote of the members of the Association.

The Association shall hold an annual conference at such time and place as the Executive Committee may direct.

The Executive Committee shall prepare a program for each meeting.

The officers of the Association shall be: President, Vice-President, and Secretary. These three, with two others elected by the Association, shall constitute the Executive Committee.

In each conference each university may have any number of representatives, but each university shall have a single vote.

No act of the Association shall be held to control the policy or line of action of any institution belonging to it.

After the adoption of this constitution, the following officers were elected for the ensuing year:

For the President of the Association—the Representative of Harvard University.

For the Vice-President—the Representative of the University of California.

For the Secretary—the Representative of the University of Chicago.

For the additional members of the Executive Committee—the Representatives of Columbia University and Johns Hopkins University.

At a meeting of the Executive Committee the Secretary was authorized to communicate with each of the institutions concerned, and to secure, if possible, the formal acceptance by each institution of membership in the Association.

It was decided by the Executive Committee to hold the next annual meeting during the last week of February in the city of Chicago. It was also voted that the meeting should not include more than four sessions, and that each university should be asked to suggest topics for discussion. The following topics were proposed: 'Migration,' 'Fellowships,' 'Subordinate Requirements for the Doctor's Degree,' 'The Printing of Dissertations.'

The Chairman of the Committee was authorized to appoint some person to prepare a statement of facts concerning each topic to be discussed. It was decided that one topic should be taken up for discussion at each session. It was voted that the Association should not appoint a representative for the Paris Exposition, and that it should not undertake at present to secure legislation with reference to the protection of higher degrees. The Federation of Graduate Clubs was given an opportunity to present statements in writing on the topics discussed in the Association.

GENERAL.

As we announced recently, a school of forestry is about to be established at Yale University. At a meeting of the corporation on March 16th, a gift of $150,000 for this purpose was acknowledged. The donors are Mr. and Mrs. J. W. Pinchot, and their sons, Mr. Gifford Pinchot, '89, and Mr. Amos. R. Pinchot, '97. The donors also authorized the use of a large tract of land in Pike County, Pa., for a summer school. Mr. Henry S. Graves, '92, has been appointed professor of forestry. Mr. Graves is assistant in the Division of Forestry, Department of Agriculture, of which Mr. Gifford Pinchot is chief.

Mr. Ezra Warner, of Chicago, has given $50,000 to Middlebury College, for a science building, the erection of which will be begun at once. Mr. Warner graduated from Middlebury College in 1861.

The Alumni of Haverford College have subscribed $40,000 for a gymnasium.

It has been decided that the new laboratory for physiology and anatomy at Cornell University, for which $80,000 was recently given, will be situated in the quadrangle east of Boardman Hall.

The bequest of about $2,000,000 by the Russian merchant, Mr. Astrachow for the establishment of a university for women at Moscow, has been accepted by the government. It is proposed first to establish faculties of medicine and of science.

The Michigan Gas Association at its annual meeting in Detroit, February 22d, raised a fund of six hundred dollars by individual subscription among the members to defray for one year the expenses, at the University of Michigan, of a graduate student who shall spend his time in research along some line of work connected with gas-making or the better utilization of by-products like coal-tar and ammonia. It is the intention of the association to support permanently a research fellowship at the University.

The corporation of Yale University has made alterations in the curriculum, enlarging the range of elective studies. The requirement of philosophy in the senior year is abandoned, and the range of electives in the sophomore year is enlarged. In the sophomore year ten subjects are offered of which five must be taken and one in addition may be taken. The subjects are, Greek, Latin, French, German, English, history, mathematics (two courses), chemistry and physics.

Arrangements have been made for a course on fish culture in connection with the Cornell University College of Forestry. It will be given during two weeks beginning May 7th at Axton in the College forest in the Adirondacks, and will be under the direction of Professor Barton W. Evermann of the United States Fish Commission. The course will consist in a series of daily lectures, with laboratory work, field excursions to the ponds, lakes and rivers, and visits to the State Hatchery at Clear Water, within a few hours of Axton. One or more lectures will be devoted to the following subjects: 1. Natural reproduction among fishes; manner of fertilization; conditions under which spawning takes place; dangers which beset the eggs, the fry and the young; necessity for artificial propagation; natural and artificial methods contrasted. 2. The species of fishes propagated artificially in America; the spawning time, place and habits of each, especially those native to the State of New York. 3. The Salmonidæ, or salmon trout and whitefish; methods of artificial propagation in detail. 4. The Black Bass and other centrarchidæ; methods of culture. 5. The Shad, Wall-eyed Pike, etc. 6. The care of fish fry. 7. Methods of shipment of eggs, fry, fingerlings and adults; how plants of fish are made. 8. Pollution of streams and lakes and fish protection. 9. Fish Culture in America, its history and results.

Courses in Commercial Education will next year be offered in the University of Michigan. (1) Diplomatic and consular education, (2) higher commercial education, (3) preparation for newspaper work, (4) preparation for pastoral work and public philanthropy, (5) instruction in public administration.

On the recommendation of Señor Barreiro, secretary for public instruction for Cuba, the school of engineering at Havana is to be reorganized.

We have already announced the resignation of the Rev. B. L. Whitman, president of Columbian University, Washington, which takes effect at the end of the present academic year. The Rev. Dr. Greene has been chosen president *pro tem.* and Professor H. L. Hodgkins (mathematics and physics) has been elected University Dean.

Dr. G. W. Myers, professor of astronomy at the University of Illinois, has resigned his chair to take charge of the department of astronomy and mathematics in the Chicago Institute.

Dr. Llewellys Barker, associate professor of anatomy at the Johns Hopkins Medical School, has accepted the chair of anatomy and neurology at the University of Chicago.

Dr. C. R. Bardeen, associate in anatomy of the University of California, has been appointed professor of this subject in the University of California.

Dr. John Ashhurst, Jr., has resigned the chair of surgery in the University of Pennsylvania.

Mr. G. T. Moody, D.Sc., F.C.S., has been appointed one of the Examiners in Chemistry in the College of Preceptors, London, in the place of Professor W. N. Hartley, F.R.S., who has retired.

Dr. Willy Bruhns, mineralogy and petrography, and Alexander Tornquist, geology and paleontology, docents at the University of Strassburg, have been appointed to associate professorships.

MSS. intended for publication and books, etc., intended for review should be sent to the responsible editor, Professor, J. McKeen Cattell, Garrison-on-Hudson, N. Y.

EDUCATIONAL VALUES.*

History is always an attractive subject because it appeals to our sympathies. There is not one of us who has not been spurred to effort by the hope of reward, intellectual, moral, social, or material. Every one has at times enjoyed the consciousness of success, or suffered the sting of failure. The history of the race is the collective history of individuals. Every individual can in imagination put himself into the place of the actors who have left strong impressions on the world and been enrolled among the makers of history.

The history of education appeals less strongly to our feelings than does the recital of deeds that determined or destroyed men's leadership in the control of their fellows. But all of us have a very real interest in some of the educational problems of the day. From some points of view it is fortunate, from others, unfortunate, that the consideration of these problems implies conflict. We have all heard about a conflict, which is said to be very sanguinary, between the advocates of scientific study and those of liberal culture. I must confess that in my earliest manhood I rushed into this affray with all the joy and enthusiasm and self-confidence that a young man feels when he knows that he must be inflicting hard blows upon the adversary,

*An address before the student body of Washington and Lee University, February 14, 1900.

even if the adversary does not think them very hard. I had spent several years in mastering a certain amount of Latin, Greek, mathematics and a few other subjects of supposed minor importance. In regard to educational values my opinions were soon very decided; and the decision was by no means in favor of the curriculum through which I had been guided by my respected but mistaken friends, the professors. It is a familiar saying that "history repeats itself." Having stepped some years ago out of the young man's shoes into those of the professor, I am now at liberty to wonder how many students will go forth from this institution next summer, ready to prove that not only I myself, but all of my esteemed friends, my colleagues in this faculty, are old fogies.

The world cannot get along without young men. Perhaps it could, but it does not, get along without the old fogies. We have all heard of the man who was born tired. I have actually seen a good many men who were born old fogies, and who became superannuated before reaching middle age. I have seen others who had passed their three score years and ten without losing the passion for progress, the willingness to take in new ideas, the intellectual alertness of their youth. But certain it is that most of us need contact with young men to keep us from becoming too self-satisfied. The college professor has other duties besides pouring out knowledge and testing his students by written examinations. He must be tested by them; he must let them see that the reciprocity is not all on one side. As soon as he begins to think that he has nothing to learn from them, it becomes the proper time for him to step aside. They are his teachers so long as he retains the capacity to learn. They may make mistakes; but so does he. They are generally disposed to be progressive, if their independence has not been stifled by too great success in acquiring the habit of depending upon authority. If there is any one characteristic by which the scientific education of to-day is conspicuously in contrast with the so-called liberal education of two generations ago, it is found in the modern inculcation of the duty to be independent and manly, to use authorities as means and not as ends, and to accept no authority whatever as beyond question.

Let us go back for a moment then into ancient history and inquire into the origin of the worship which some of us were taught to offer to the fair goddess of liberal culture, the worship of a name while the actual culture was anything but liberal. It is not my wish to criticise our own conditions here; for happily the Washington and Lee University of to-day is so different from the Washington College of our grandfathers that they would find themselves much puzzled, perhaps even shocked, if they could step forth from their graves and visit us. The idea with which they were saturated was that the chief end of all education was discipline, and that a certain small number of subjects were inherently better for discipline than all else that related to human interests. If the young man were drilled until he could memorize a Greek play, a Latin oration, and a chapter of calculus, he was conventionally the possessor of liberal culture. The allowance was, as we now believe, very illiberal; but it was all that he could get. There were three liberal professions, divinity, law, and medicine, one of which he must select, but not one of which involved any special application of what he had studied in college. Vicarious discipline was, therefore, the sacred means by which he was to attain his earthly salvation.

Such an idea of education was accepted quite generally and cheerfully, because it was traditional and therefore respectable. It had been usual not only during the previous generation but during a hundred generations. Among the ancient Greeks the body was educated by gymnastic exercises, but this was confined chiefly to the aristocracy; for useful labor, involving bodily exercise and hence muscular development, was looked upon as menial and degrading. Intellectual education was regarded from the same standpoint. It might be a badge of gentility, but to seek useful knowledge was no more an educational object than to learn useful arts. Intellectual gymnastics for its own sake was a source of pleasure. To regard it as a source of profit would be to degrade it. "Not the game, but the excitement of the chase; not the truth, but the exhilaration of its pursuit, were the mottoes of culture. Under these circumstances no vulgar question of economy could arise; mental power was ostentatiously wasted, and with the necessary consequences,—truth unsought was not found; the ends of culture being ignored, there was neither conquest of nature nor progress of society."

Such ideals have continued potent to the present day. In mediæval times they were cultivated in the monasteries. It was for the support of them that universities gradually became organized. They are still dominant at Oxford and Cambridge in England, and in the universities of Germany, France and Italy. Their great value is readily conceded. If they constituted all that could be included in modern education, they would still be worth preserving and fostering. Under such ideals were educated some of the greatest men whose labors have advanced physical science, such as Newton, Huyghens and Laplace. The craving of humanity for intellectual exercise without reference to bread winning is as natural as the craving for food, or bodily activity, or companionship, the love of home, of family, or of country. The love of literature, of art, of science for its own sake, is conspicuously worthy of all commendation and encouragement. To know the best that has been thought and spoken and written, to appreciate the noblest and purest that the painter's brush has left upon canvas, to be capable of taking in the ideas and complex emotions that are conveyed in song and symphony, to apprehend the order and harmony that pervades a universe that is continually undergoing evolution in accordance with law—these are objects well worthy of our best efforts, irrespective of the remuneration that can be expressed in money or material power.

But the culture so eminently worthy of our seeking is not all that the world is justified in holding to be valuable. Why should such training be given in youth? It is not merely because the young are non-producers in society, but because they are more capable of modification than after maturity is reached. That the education to be given in youth should be a preparation for manhood is an idea that does not seem to have been well grasped by the educators in ancient or even comparatively recent times. Education was long reserved for the priesthood, rather than for the manhood of the people. Its underlying idea was the preservation of scholastic authority rather than the development of intellectual independence and moral power. It was intended to be a luxury for the few, while the masses were expected to keep on toiling in ignorance as had been done throughout untold centuries. The education of the English universities, even of this year 1900, is essentially aristocratic. Great stress is laid upon certain subjects, not because they afford the best culture, but because they are traditionally genteel, not because they confer power, but because they have long been fostered by the nobility. Even the army, officered by aristocrats who substituted gentility for military knowledge, has been this winter betraying its organic weakness in South Africa; and the liberally educated English have yet (February 14, 1900) to herald their first victory over the despised Boers, after four months of disastrous grappling. They will in time be victorious, but not by the application of what they have been taught through genteel traditions.

The educational system of a country should be adjusted to the needs of the majority of its people, and not be controlled by the nobility, whether this term be applied to the aristocracy of inherited rank, as in England, or of wealth, as in America. As soon as the question of educational values arises, therefore, we must ask ourselves, with candor and with utter disregard of genteel traditions, what kinds of knowledge are best fitted to develop mental, moral, and material power in our young men, recognizing the conditions of civilization as they exist to-day in the most prosperous parts of America. We are not to decry liberal culture; but we are abundantly justified in criticising the traditional limitations which have restricted the name of liberal culture quite arbitrarily to a certain group of studies. What is the ground upon which these studies have been called liberal? It is that they are now, and have long been, genteel; that they do not aim to help their votaries to make money; that their object is to produce such intellectual and social polish as money can not buy; that the stored-up capital which they represent must not yield interest in money, but only in culture; it must be totally independent of all commercial values.

This ideal was almost completely fulfilled during the many centuries of its dominance up to the nineteenth century. But commerce is stronger than an ideal. Is literary culture to-day without its pecuniary rewards? Is fine art practiced purely for the purpose of expressing the beautiful? So far as activity is expended for the cultivation of the true, the beautiful, and the good, the culture is liberal. So soon as the results of such activity cease to be given freely to the world, and become devoted to the acquisition of money, the name liberal ceases to be applicable. There are hundreds of men and women whose interests in college were concentrated upon literature, classics and history, and who apply the results of the mental discipline thus acquired, and the knowledge thus stored up, directly to the money-making business of writing novels. There are thousands more who are well paid for contributing to the newspapers such fiction as is euphemistically called news. All of it is called literary work, and the writers receive the credit of dwelling in an atmosphere of liberal culture. Fortunes have been made by judicious response to the popular demand for light literature, and the liberal culture disseminated is directly proportional to the liberal payment laid down in silver and gold. On the other hand there is an increasing number of young men who annually come forth from American universities, and yet more from German universities, whose time has been devoted to studies that by contrast are called scientific. They spend time and labor in the pursuit of science for its own sake. The results of their investigations are published in journals for which the general public has no use; and they receive no compensation for such contributions except the satisfaction of making themselves and their work known to the so-called scientific world. Their inquiries relate to subjects which have no commercial importance, and their object is without pay to enlarge the boundaries of human knowledge. Their stimulus is the pleasure of discovery, of investigation, of successful intellectual activity. The recognition they receive is such as money cannot possibly buy.

Nor have these scientific investigators been confined to the present century. Newton's Principia marked an epoch in science. It brought no money to its author, though succeeding generations have built upon it the remunerative science of navigation. Huyghens, Young, and Fresnel established the wave theory of light, the foundation of the now useful science of optics. They gave the products of their labor freely to the world, living economically, and dying with very small possessions. Gauss and Weber established the modern science of magnetism, while Volta, Oerstedt, Ampere, Ohm, Faraday, Henry, and Maxwell worked together and in succession to make electricity an exact science. They received no pecuniary rewards, but we to-day are reaping the fruits of their labors in the electrical industries that afford employment to a million of men and absorb hundreds of millions of capital. Shall we declare that these original investigators, these men of genius, were not representatives of liberal culture, merely because the subjects upon which their brain power was expended happened not to relate to literature, or linguistics, or art, or history? Some of these much decried scientific men, such as Tyndall, Huxley, and Darwin proved themselves to be adepts in the art of writing clear and forcible English. Were they devoid of culture? Tyndall knew little of Latin and nothing of Greek, but in the battle where tradition was arrayed against truth he displayed such culture and such vigor as to make him a match for more than one classically educated bishop.

The attempt to establish a line of division between science and liberal culture is an anachronism. We have outgrown the authority of our fathers who accepted the exclusive gentility of a certain group of studies and shrugged their shoulders at the young parvenue whom they called science. Let me here express my sympathy with the protest directed against the abuse of this comprehensive word, science. If the meaning of a word is determined by etymology, science merely means knowledge. It makes no difference whether the subject be chemistry, physics, economics, or philosophy; if the knowledge be definite, consistent and organized, it is science. If it be vague, if mere fancy is accepted as a substitute for fact, if dogma is balanced against demonstration, it is not science, it is not knowledge, though it may be brilliant imagination. But the meanings popularly attached to words are not determined by etymology. Whether rightly or wrongly, the word science has become restricted by tacit popular agreement to our knowledge of things in contrast with our knowledge of words or our speculations about ideals. When we appeal to nature our conclusions need verification before final acceptance. Those methods of investigation which imply verification are conventionally called scientific. If they become successfully applied to any subject whatever, the knowledge thus acquired becomes scientific.

Thanks to the scientific spirit that has leavened all modern institutions of learning, the scientific method is now increasingly applied to subjects which were formerly bound down by the shackles of tradition. It has raised to a high and dignified level subjects which were not recognized a generation ago as having any place in a liberal education. Prominent among these new sciences, these new elements of liberal culture, are political science and economics, equal in importance with physics and chemistry, even if they do not call for laboratory work. These new sister sciences may not be so traditionally genteel as the prim old sisters called classics and mathematics, but they are fresh, smiling and apparently quite irresistible.

The extent to which the old and traditional culture studies are giving place to modern and equally liberal culture studies is well shown by reference to last year's statistics at Yale University, an institution which was long one of the strongholds of conservatism. In all the higher educational institutions of the present day more or less liberty is accorded the student to elect at least some of the studies to which his time is to be devoted. The most popular subject at Yale last year was political economy, which was elected by 957 students. History was elected by 822, English by 529, philosophy by 398, modern languages by 266, classics, including both Latin and Greek by 172, and mathematics by 37. Under the head of natural science, including astronomy, physics, chemistry, geology and biology, the number of elections was 257. This certainly does not look as if the representatives of science, using this term in its conventional sense, are in a position to smile, either contemptuously or patronizingly, upon the devotees to so-called liberal culture.

The object of education is to make each one of us as nearly perfect a human being as he is capable of becoming. The great majority of those who begin to receive an education are restricted to elementary work. The determination of educational values depends in every case upon individual needs. Good mental discipline can be acquired by the systematic and earnest study of any subject whatever if the student has a living conviction of its importance, and the teacher has brains, enthusiasm, and skill. Any subject may be made a means of liberal culture if both teacher and student are stimulated by the love of knowledge. The law school, the medical school, the technological school are as necessary for the higher grades of professional culture as the college is for general culture. The student is not harmed but healthfully stimulated by his recognition of the vital importance to himself of what is drawing forth his best efforts. Let us welcome every new opportunity that is given our young men to adapt themselves to the requirements of modern life. No amount of declamation or invective can displace physical science from its present high position. Those of us who are devoted to science are willing and glad to clasp hands with all who are ready to go with us onward and upward.

No classification of educational values has been given that is superior to that that was expressed about forty years ago by one of the greatest of modern thinkers, Herbert Spencer. In the order of their relative importance the leading kinds of activity which constitute human life are grouped as follows:

1. Those which directly minister to self-preservation.

2. Those which, by securing the necessaries of life, indirectly minister to self-preservation.

3. Those which have for their object the rearing and training of the young.

4. Those which are involved in the maintenance of proper social and political relations.

5. Those which make up the leisure part of life, devoted to the gratification of the tastes and feelings.

The best education is the best preparation for all of these activities, its aim being to maintain a due proportion between the degrees of preparation in each. The order of relative importance is obviously the inverse of the order of diversity and complexity. It is not surprising therefore that up to a very recent time the work of educators has been confined chiefly to the last one of the groups of activities enumerated by Spencer. But in spite of educational traditions the world has lately been demanding attention to the other groups, and modern science as taught in our foremost universities and technical schools is the response to that demand. Mr. Spencer considers the educational needs implied for the best exercise of all these activities; and in answer to the question—What knowledge is most worth?—the answer is Science.

"For direct self-preservation, or the maintenance of life and health, the all important knowledge is—science. For that indirect self-preservation which we call gaining a livelihood, the knowledge of greatest value is—science. For the due discharge of parental functions, the proper guidance is to be found only in—science. For that interpretation of national life, past and present, without which the citizen cannot rightly regulate his conduct, the indispensable key is—science."—economics and political science. "For the most perfect production and highest enjoyment of art in all its forms the needful preparation is still—science. And for purposes of discipline, intellectual, moral, religious, the most efficient study is still—science."

It is not to be expected that these conclusions will be accepted by all to whom they are addressed. I should be the last to decry the importance of language study, of history, art, and philosophy. I emphatically emphasize the importance of national education in economics and political science. We are sadly in need of better political teachers than a majority of those who during the last few years have been the leaders in American politics. But I protest against the implication that liberal culture is suffering at the hands of either the active workers or the leading teachers in science. So long as human needs and human tastes are diversified must there be corresponding diversity in education. Let each of us recognize what is good in our neighbor, let us cheerfully and cordially acknowledge the value of his contribution to human welfare. Let us remember that there are others besides scientific men who are progressive, and that the boundaries of knowledge are without limit.

Within the present century one of the greatest mathematicians and astronomers that the world has ever known, Laplace, lay on his dying bed in Paris. His last words were: "Ce que nous savons est peu de choses; ce que nous ignorons est immense." It takes a philosopher to recognize the immensity of his own ignorance. If Laplace could use those words as he fell asleep, why can we not at least follow him and remain at peace with each other while striving to do our share in increasing human knowledge? Linguist and engineer, historian and chemist, economist and physicist, metaphysician and mathematician, our aims radiate from a common center; but friendly and faithful as we may be to each other, our ignorance will still continue to be immense.

W. LE CONTE STEVENS.

---

*PICTURES PRODUCED ON PHOTOGRAPHIC PLATES IN THE DARK.**

I THINK I may fairly assume that every one in this theater has had his photograph taken, and consequently must have some idea of the nature of the process employed. I have, therefore, only to add, with regard to what is not visible in the process of taking the picture, that the photographic plate is a piece of glass or such like body, coated on one side by an adhesive paste which is acted on by light, and acted on in a very remarkable manner. No visible change is produced, and the picture might remain latent for years, but place this acted-on plate in a solution, of, say pyrogallol, and the picture appears. The subsequent treatment of the plate with sodium hyposulphite is for another purpose, simply to prevent the continuance of the action when the plate is brought into the light. Now, what I purpose demonstrating to you to-night is that there are other ways of producing pictures on photographic plates than by acting on them by light, and that by these other

* Address before the Royal Institution of Great Britain.

means a latent picture is formed, which is rendered visible in precisely the same way as the light pictures are.

The substances which produce on a photographic plate these results so strongly resembling those produced by light, are, some of them, metallic, while others are of vegetable origin. At first it seemed very remarkable that bodies so different in character should act in the same way on the photographic plate. The following metals—magnesium, cadmium, zinc, nickel, aluminium, lead, bismuth, tin, cobalt, antimony—are all capable of acting on a photographic plate. Magnesium most strongly, antimony but feebly, and other metals can also act in the same way, but only to a very slight extent. The action in general is much slower than that of light, but under favorable conditions a picture may be produced in two or three seconds.

Zinc is nearly as active as magnesium or cadmium, and is the most convenient metal to experiment with. In its ordinary dull state it is without the power of acting on a photographic plate, but scratch it or scrape it, and it is easy to prove that the bright metal is active. I would say that all the pictures which I have to show you, by means of the lantern, are produced by the direct action of the metal, or whatever the active body may be, on the photographic plate, and that they have not been intensified or touched up in any way. This first slide is the picture given by a piece of ordinary zinc which has been rubbed with some coarse sand-paper, and you see the picture of every scratch. Here is a piece of dull zinc on which some circles have been turned. It was exposed to the photographic plate for four hours at a temperature of 55°C. In the other cases, which are on a larger scale, a zinc stencil was polished and laid upon a photographic plate, and you see where the zinc was in contact with the plate much action has occurred. In another case a bright zinc plate was used, and a Japanese stencil interposed between it and the photographic plate, and a very strong and sharp picture is the result. The time required to produce these zinc pictures varies very much with the temperature. At ordinary temperature the exposure would have to be for about two days, but if the temperature was, say, 55°C., then half to three-quarters of an hour might be sufficient. Temperatures higher than this cannot be used except for very short times, as the photographic plate would be damaged. Contact between the zinc and photographic plate is not necessary, as the action readily takes place through considerable distances. Obviously, however, as you increase the distance between object and plate, so you decrease the sharpness of the picture, as is shown by the following pictures, which were taken respectively at a distance of 1 mm. and 3 mm. from the scratched zinc surface. The appearance of the surfaces of different metals varies, and the following slides show the surface of a plate of bismuth, a plate of lead and one of aluminium. On the next slide are the pictures produced by similar pieces of pure nickel and cobalt, and it clearly shows how much more active in this way nickel is than cobalt. Many alloys, such as pewter, fusible metal, brass, etc., are active bodies, and in the case of brass the amount of action which occurs is determined by the amount of zinc present. Thus you will see that a brass with 30 per cent. of zinc produces hardly any action on the photographic plate, but when 50 per cent. of zinc is present there is a fairly dark picture, and when as much as 70 per cent. is present a still darker picture is produced.

The second class of bodies which act in the same way on a photographic plate are organic substances, and belong essentially to the groups of bodies known as terpenes. In trying to stop the action of metallic zinc, which I thought at the time might arise from vapor given off by the metal, copal varnish was used, but in place of stopping the action it was found to increase it, and this increase of activity was traced to the turpentine contained in the varnish. In experimenting with liquids it is convenient to use small shallow circular glass vessels such as are made for bacteriological experiments, the plate resting on top of the vessel, and the amount of liquid in the vessel determining the distance through which the action shall take place. The following slide, produced in this way, shows how dark a picture ordinary turpentine produces. All the turpenes are active bodies. Dipentine is remarkably so; in a very short time it gives a black picture, and if the action be continued, the dark picture passes away, and you then have a phenomenon corresponding to what photographers call reversal. The strong smelling bodies known as essential oils, such as oil of bergamot, oil of lavender, oil of peppermint, oil of lemons, etc., are all active bodies, and all are known to contain in varying quantities different terpenes; therefore ordinary scents are active bodies, and this is shown by the following pictures produced by eau de Cologne, by cinnamon, by coffee, and by tea. Certain wines also act in the same way: Sauterne gives a tolerably dark picture, but brandy only a faint one. Other oils than these essential ones are also active bodies: linseed oil is especially so; olive oil is active, but not nearly as much so as linseed oil; and mineral oils, such as paraffine oil, are without action on the photographic plate.

Interesting results are obtained with bodies which contain some of these active substances; for instance, wood will give its own picture, as is shown by the following slides: the first is a section of a young spruce tree, the next a piece of ordinary deal, and the third of an old piece of mahogany. Again, the next slide you will recognize as the picture of a peacock's feather. There is much interest in these pictures of feathers, as they distinguish the brilliant interference colors from those produced by certain pigments; the beautiful blue in the eye of the peacock's feather is without action on the photographic plate. Butterflies' wings, at least some of them, will draw, as you see, their own pictures. Linseed oil, which is a constituent of all printing ink, makes it an active body, and it can, like the zinc and other active bodies, act through considerable distances. In the picture before you the ink was at a distance of one inch from the plate, and the next slide shows what a remarkably clear and dark picture ordinary printing can produce. As the composition of printing ink varies so does its activity, and here are pieces of three different newspapers which have acted under the same conditions on the same plate, and you see how different the pictures are in intensity. Printed pictures, of course, act in the same way—here is a likeness of Sir H. Tate taken from 'The Year's Art.' The pictures and printing in *Punch* always print well; so does the yellow ticket for the Friday evening lectures at the Royal Institution; also the rude trade-mark on Wills's tobacco, and it is of interest because the red pigment produces a very clear picture, but the blue printing is without action on the plate.

An interesting and important peculiarity of all these actions is that it is able to pass through certain media; for instance, through a thin sheet of gelatin. Here are two plates of zinc; both have been scratched by sand-paper; one is laid directly on the photographic plate, and the other one has a sheet of gelatin, its color is of no note, laid between it and the sensitive plate; the picture in this case is, of course, not so sharp as when no gelatin is present, but it is a good and clear likeness of the scratches.

Celluloid is also a body which allows the action to pass through it, as is seen in this picture of a piece of perforated zinc, a picture which was produced at ordinary temperatures. Gold-beaters' skin, albumen, collodion, gutta-percha, are also bodies which are transparent to the action of the zinc and the other active bodies. On the other hand, many bodies do not allow the transmission of the action through them; for instance paraffin does not, and among common substances writing-ink does not, as is easily shown by placing ordinary paper with writing on it between the active body and the photographic plate. The active body may conveniently be either a plate of zinc or a card painted with copal varnish and allowed to dry, or a dish of drying oil. The picture of an ordinarily directed envelope shows this opacity of ink well. It is a property long retained by the ink, as this picture of the direction of a letter, written in 1801, shows; also this letter of Dr. Priestley's, dated 1795; and here is also some very faded writing of 1810, which still gives a very good and clear picture. Even if the writing be on parchment, the action passes through the parchment, but not through the ink, and hence a picture is formed.

With bodies which are porous, such as most papers, for instance, the action passes gradually through the interstices, and impresses the plate with a picture of the general structure of the intervening substance. For instance, the following pictures show the structure and the water-mark of certain old and modern writing-papers. Some modern writing-papers are, however, quite opaque; but usually paper allows the action to take place through it, and combining this fact with the fact of strong activity of the printing-ink, the apparently confused appearance produced on obtaining a picture from paper with printing on both sides is accounted for, as the printing on the side away from the photographic plate, as well as that next to it, prints through the paper, and is, of course, reversed.

I hope I have now given you a clear idea how a picture can be produced on a photographic plate in the dark, and the general character and appearance of such pictures. I now pass on to the important question of how they are produced. Moser suggested fifty years ago that there was 'dark light,' which gave rise to pictures on polished metallic plates, and lately it was suggested that pictures were produced by vapor given off by the metals themselves; the explanation, however, which I have to offer you is, I think, simpler than either of these views, for I believe that the action on the photographic plate is due to the formation of a well-known chemical compound, hydrogen peroxide, which undergoing decomposition acts upon the plate and is the immediate cause of the pictures formed. The complicated changes which take place on the sensitive plate I have nothing to say about on the present occasion, but I desire to convince you, that this body, hydrogen peroxide, is the direct cause of these pictures produced in the dark. Indirect proof has to be resorted to. Water cannot be entirely excluded, for an absolutely dry photographic plate would probably be perfectly inactive, and as long as water is present peroxide of hydrogen may be there also. But what are the conditions under which these pictures are formed? Only certain metals are capable of producing them. This list of active metals which I have mentioned to you was determined solely by experiment, and when completed it was not evident what common property bound them together. Now, however, the explanation has come for these are the very metals which most readily cause, when exposed to air and moisture, the formation of this body peroxide of hydrogen. Schönbein showed as long ago as 1860 that when zinc turnings were shaken up in a bottle with a little water hydrogen peroxide was formed, and the delicate tests which we now know for this body show that all the metals I named to you not only can in the presence of moisture produce it, but that their power of doing so follows the same order as their power of acting on a photographic plate. Again, what happened with regard to the organic bodies which act on the photographic plates? I have already mentioned that in experimenting with the metals it was accidentally observed that copal varnish was an active substance producing a picture like that produced by zinc, and that the action was traced to the turpentine present; again a process very much like groping in the dark had to be carried on in order to determine which were active and which inactive organic bodies, and the result obtained was that the active substances essentially belonged to the class of bodies known to chemists as terpenes. Now a most characteristic property of this class of bodies is that in presence of moisture and air they cause the formation of hydrogen peroxide, so that whether a metal or an organic body be used to produce a picture, it is in both cases a body capable, under the circumstances, of causing the formation of hydrogen peroxide. Passing now to experimental facts, which confirm this view of the action on sensitive plates, I may at once say that every result obtained by a metal or by an organic body can be exactly imitated by using the peroxide itself. It is a body now made in considerable quantity, and sold in solution in water. Even when in a very dilute condition it is extremely active. One part of the peroxide diluted with a million parts of water is capable of giving a picture. It can, of course, be used in the glass dishes like any other liquid, but it is often convenient not to have so much water present; and then it is best to take white blotting paper, wet it in the solution of the peroxide, and let it dry in the air. The paper remains active for about twenty-four hours; or, what is still better, take ordinary plaster of Paris, wet it with the peroxide solution, and let it set 'in a mould' so as to get a slab of it. This slab increases in activity for the first day or two after making, and retains its activity for a fortnight or more. Such a slab will give a good and dark picture in three or four seconds.

To show how similar the pictures produced by the peroxide and those by zinc are, pictures of a Japanese paper stencil, which had been paraffined to make it quite opaque, have been made by both processes, and are shown with other instances in which turpentine was used in the following slides. It is also very easy to obtain good pictures with the peroxide alone of the structure of paper, etc.; see, for instance, this one of a five-pound note and these of lace. Again, the strict similarity between the action of the peroxide and that of the metals and organic bodies is further shown by the fact that its action passes through the same media as their action does; and here are good pictures formed by the action of the peroxide after passing through a sheet of these substances. How this singular transmission can be explained, I have treated of elsewhere, and time does not allow of my discussing the matter to-night.

There are many ways in which the bright, active zinc surface can be modified. Draw your finger across it, press your thumb upon it, and you stop its activity, as is shown by the picture it will give. Lay a printed paper on the zinc, and let the contact continue for three-quarters of an hour, at a temperature of 55°, then bring the zinc in contact with a sensitive plate, a picture of the printing is formed, but allow the contact between the zinc and printing to continue for eighteen hours at the same temperature, and the picture then given by the zinc is the reverse of the former one.

Where the ink has been is now less active than the rest of the plate. Here are slides which show these positive and negative pictures. Another way of modifying the zinc surface is interesting. You have seen that the ordinary zinc surface which has been exposed to air and moisture is quite inactive, but if a bright piece of zinc be immersed in water for about twelve hours, the surface is acted on; oxide of zinc is formed, showing generally a curious pattern. Now if the plate be dried, it will be found that this oxide is strongly active, and gives a good picture of the markings on the zinc. The oxide evidently holds, feebly combined or entangled in it, a considerable quantity of the hydrogen peroxide, and it requires long drying or heating to a higher temperature to get rid of it. Also, if a zinc plate be attacked by the hydrogen peroxide, the attacked parts become more active than the bright metal. Thus place a stencil on a piece of bright zinc, and expose the plate to the action of an active plaster of Paris slab, or to active blotting-paper for a short time, then, on removing the stencil, the zinc plate will give a very good picture of the stencil. Any inactive body—for instance, a piece of Bristol board or any ordinary soft paper—can be made active by exposing it above a solution of peroxide, or, more slowly, by exposing it to a bright zinc surface. If, for instance, a copper stencil be laid on a piece of Bristol board, and a slab of active plaster of Paris be placed on the stencil for a short time, the Bristol board will even, after it has been removed from the stencil for some time, give a good picture of the stencil. Drying oil and other organic bodies may be used in the same way to change the paper. A curious case of this occurred in printing a colored advertisement cut out of a magazine, for there appeared printing in the picture which was not in the original. This printing was ultimately traced to an advertisement on the opposite page, which had been in contact with the one which was used; thus this ghostly effect was produced.

I believe, then, that it is this active body, hydrogen peroxide, which enables us to produce pictures on a photographic plate in the dark. There are many other curious and interesting effects which it can produce, and which I should like to have shown you, had time permitted.

I would only add that this investigation has been carried on in the Davy Faraday Laboratory of this Institution.

WILLIAM JAMES RUSSELL.

*DEGENERATION IN THE EYES OF THE COLD-BLOODED VERTEBRATES OF THE NORTH AMERICAN CAVES.**

"DEGENERATION," says Lankester, "may be defined as the gradual change of the structure in which the organism becomes adapted to less varied and less complex conditions of life; whilst elaboration is a gradual change of structure in which the organism becomes adapted to more and more varied and complex conditions of existence."

Degeneration may affect the organism as a whole or some one part. I propose to speak not on degeneration in general but to give a concrete example of the degeneration of the parts of one organ.

The eyes of the blind vertebrates of North America lend themselves to this study admirably because different ones have reached different stages in the process, so by studying them all we get a series of steps through which the most degenerate has passed. This enables us to reach conclusions

* Presidential address at the meeting of the Indiana Academy of Sciences, Dec. 27, 1899. The detailed account of the eyes, whose general features are given here, has in part been published in Roux's Archiv f. Entwickelungsmechanik, VIII., and will in part be published in the Proceedings Am. Microscopical Society for 1899.

that the study of an extreme case of degeneration would not give.

I shall confine myself to the cave salamanders and the blind fishes (Amblyopsidæ) nearly all of which I have visited in their native haunts. The salamanders are introduced to illuminate some dark points in the degeneration of the eyes of the fishes and to emphasize a fact that is forcing itself forward with increasing vehemence, *i. e.*, that cross-country conclusions are not warrantable, that the blind fishes form one group and the salamanders other groups, and that, however much one may help us to understand the other, we must not expect too close an agreement in the steps of their degeneration under similar conditions.

There are three cave salamanders in North America.

1. *Spelerpes maculicauda* is found generally distributed in the caves of the Mississippi valley. It so closely resembles *Spelerpes longicauda* that it has not until more recent years been distinguished from the latter which has an even wider epigæan distribution. There is nothing about the structure of this salamander that marks it as a cave species but its habits are conclusive.

2. *Typhlotriton* is much more restricted in its distribution, being confined to a few caves in southwestern Missouri. I have taken its larvæ at the mouth of Rock House cave in abundance. In the deeper recesses of Marble cave I secured both young and adult. This is a cave species of a more pronounced type. The very habit that accounts for the presence of salamanders in caves has been retained by this one. I found some individuals hiding (?) under rocks and in the aquarium their steriotropic nature manifests itself by the fact that they crawl into glass tubing, rubber tubing or under wire screening. In the eye of this species we have some of the early steps in the process of degeneration.

3. *Typhlomolge* has been taken from a surface well near San Marcos, Texas, and from the artesian well of the U. S. Fish Commission which taps a cave stream about 190 feet from the surface. It has also been seen in the underground stream in Ezel's cave near San Marcos. It was also reported to me from south of San Antonio, Texas. This is distinctly and exclusively a cave species and its eyes are more degenerate than those of any other salamander, including the European Proteus.*

The Amblyopsidæ are a small family of fresh water fishes and offer exceptional facilities for the study of the steps in the degeneration of eyes. There are at least six species and we have gradations in habits from permanent epigæan species to species that have for ages been established in caves.

The species of *Chologaster* possess well developed eyes. One of them, *C. cornutus*, is found in the coast streams of the southeastern States; another, *C. papilliferus*, is found in some springs in southwestern Illinois, while the third, *C. agassizii* lives in the cave streams of Kentucky and Tennessee.

The other members of the family are cave species with very degenerate eyes. They represent three genera which are descended from three epigæan species. *Amblyopsis*, the giant of the race, which reaches 135

*It may be noticed that the eyes of the western *Typhlotriton* are more degenerate than those of the cave *Spelerpes* of wider distribution. Further the eyes of the Texan *Typhlomolge* are more degenerate than those of the Missouri *Typhlotriton*. Now similarly the Missouri blind fish *Troglichthys* has eyes in a much more advanced state of degeneration than the Ohio valley blind fishes. It is possible that the explanation is to be found in the length of time the caves in these regions have been habitable. During the glacial epoch the caves of the Ohio valley were at or near the northern limit of vegetation. The Missouri caves, if affected by glaciation, must have become habitable before those of the Ohio valley, while those of Texas were probably not affected at all.

mm. in length, is found in the caves of the Ohio Valley. *Typhlichthys* is also found in the Ohio Valley but chiefly south of the Ohio river. But a single specimen has been found north of the Ohio and this represents a distinct species. *Troglichthys* which is found in the caves of Missouri, has been in caves longer than its relatives if the degree of degeneration of its eyes is a criterion.

Before dealing with the degeneration of the eye a few words are in order on the normal structure of the organ under consideration.

In the normally developed eye we may distinguish a variety of parts with different functions. These are:

A. Organs for protection like the lid and orbits.

B. Organs for moving the eye to enable it to receive direct rays of light. In the cold-blooded vertebrates these consist of four rectus muscles and two oblique.

C. Organs to support the active structures, the fibrous or cartilaginous sclera.

D. The eye itself consisting of:

1. Parts for transmitting and focusing light; the cornea, lens and vitreous body.

2. Parts for receiving light and transforming it to be transmitted to the brain; the retina.

3. A part for transmitting the converted impression to the brain; the optic nerve.

Some of these as the muscles, retina and optic nerve are active while others, the protective and supporting organs, are passive.

A. In the Amblyopsidæ the skin passes directly over the eye without forming a free orbital rim or lid. The skin over the eye in *Chologaster* is much thinner than elsewhere and free from pigment. In the other species of the family the eye has been withdrawn from the surface. In these it lies deep beneath the skin and the latter where it passes over the eye, has assumed the structure normal to it in other parts of the head.

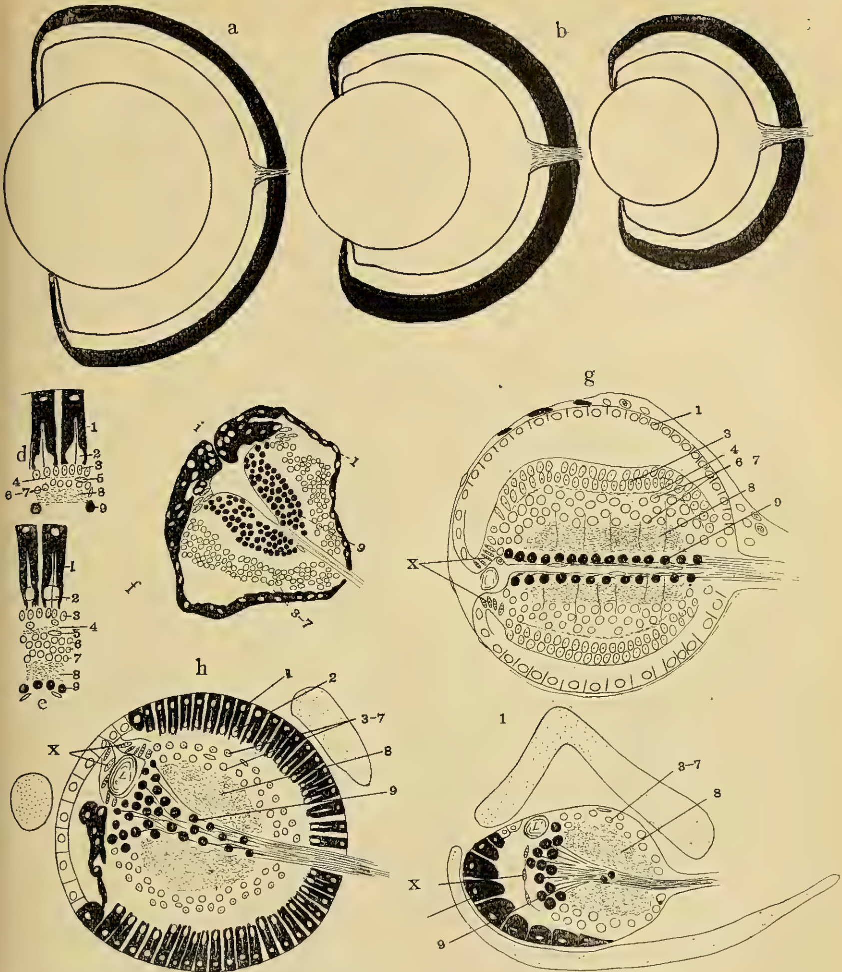
In the salamanders we have a perfect gradation in the matter of the eye-lids. In *Spelerpes* a free orbital rim is present in every respect like that found in epigæan salamanders. In *Typhlotriton* the lids are closing over the eye. The slit between the upper and lower lid is much shorter than normally and the upper lid overlaps the lower. The conjunctiva is still normal. The eye of this species is midway between the normal salamander eye and that of *Typhlomolge*, in which a slight thinning of the skin is all there is to indicate its former modification over the eye.

B. The muscles to change the direction of the eye-ball show complete gradations from perfect development to total disappearance.

In the species of *Chologaster* all the muscles are normally developed. In *Amblyopsis* the muscles are unequally developed, but one or more are always present and can be traced from their origin to the eye. In *Troglichthys*, the distal halves of the muscles, the parts nearest the eye have been replaced by connective tissue fibers, *i. e.*, a tendon has replaced part of the muscle. Here we have a step in advance in the degeneration found in *Amblyopsis* and no instance was noticed where *all* the muscles of any eye were even developed in the degree described. In *Typhlichthys* the muscles have all disappeared.

In *Typhlomolge* the muscles have disappeared; in the other salamanders they are present.

C. The sclera is differently developed in *Chologaster*, and there is but little modification in the species with more degenerate eyes except that in *Amblyopsis* and *Troglichthys*, where cartilaginous bands were evidently present in the epigæan ancestors. These bands have persisted in a remarkable degree, being much too large for the minute eyes with which they are connected. In *Troglichthys* they form a hood over the front



a to *i*. Diagrams of the eyes of all the species of the Amblyopsidæ and of Typhlomolge.

of the eye, and various projections and angles in their endeavor to accommodate themselves to the small structure which they cover.

This is in striking contrast to the conditions in *Typhlotriton*, where but a slight nodule of cartilage remains and this is very frequently absent in the adult, while in the larva of the same species a cartilaginous band extends almost around the equator of the eye. The different effect of degeneration in the Amblyopsidæ and the salamanders could not be more forcibly illustrated than by the scleral cartilages.*

D. The eye as a whole and its different parts may now be considered.

1. The dioptric apparatus.

The steps in degeneration of the eye in general are indicated in the accompanying figure.

The most highly developed eye is that of *Chologaster papilliferus*. The parts of this eye are well proportioned, but the eye as a whole is small, measuring less than one millimeter in a specimen 55 mm. long. The proportions of this eye are symmetrically reduced if it has been derived from a fish eye of the average size, but the retina is much simpler than in such related pelagic species as *Zygonectes*. The simplifications in the retina have taken place between the outer nuclear and the ganglionic layers. The pigment layer has not been materially affected. These facts are exactly opposed to the supposition of Kohl that the retina and the optic nerve are the last to be affected and that the vitreous body and the lens cease to develop early. In *Chologaster papilliferus* the latter parts are normal, while the retina is simplified. That the retina is affected first is proved beyond cavil by *Chologaster cornutus*. The vitreous body and the lens are here larger than *papilliferus*, but the retina is very greatly simplified. *Cornutus*, it must be borne in mind, lives in the open. The eye of the cave species *Chologaster agassizii* differs from that of *papilliferus* largely in size. There is little difference in the retinas except the pigmented layer, which is about 26 per cent. thinner in *agassizii* than in *papilliferus*.

* The presence of a cartilaginous band in the young is, possibly, a larval character, and its absence in the adult has, in that case, no bearing on degeneration.

There is a big gap between the lowest eye of *Chologaster* and the highest eye of the blind members of the Amblyopsidæ. The lens in the latter has lost its fibrous nature and is merely an ill-defined minute clump of cells scarcely distinguishable in the majority of cases. The vitreous body of the latter species is gone with perhaps a trace still remaining in *Typhlichthys*. With the loss of the lens and the vitreous body the eye collapsed so that the ganglionic layer formerly lining the vitreous cavity has been brought together in the center of the eye.

The layers of the retina in *Typhlichthys* are so well developed that could the vitreous body and lens be added to this eye it would stand on a higher plane than that of *Chologaster cornutus*, exclusive of the cones and pigmented layer. It is generally true that at first the thickness of the layers of the retina is increased as the result of the reduction of the lens and vitreous body and the consequent crowding of the cells of the retina whose reduction in number does not keep pace with the reduction in the dioptric apparatus in total darkness.

If we bear in mind that no two of the eyes represented here are members of a phyletic series, we may be permitted to state that from an eye like that of *cornutus*, but possessing scleral cartilages, both the eyes of *Amblyopsis*, and *Troglichthys* have been derived and that the eye of *Amblyopsis* represents one of the stages through which the eye of *Troglichthys* passed. The eye of *Amblyopsis* is the eye of *C. cornutus* minus a vitreous body with the pupil closed and with a minute lens or none at all. The nuclear layers have gone a step further in their degeneration than in *cornutus*, but the greatest modification has taken place in the dioptric arrangements.

In *Troglichthys* even the mass of ganglionic cells present in the center of the eye as the result of the collapsing after the removal of the vitreous body has vanished. The pigmented epithelium, and, in fact, all the other layers, are represented by mere fragments.

The eye of *Typhlichthys* has degenerated along a different line. There is an almost total loss of the lens and vitreous body in an eye like that of *papilliferus* without an intervening stage like that of *cornutus*, and the pigment layer has lost its pigment, whereas in *Amblyopsis* it was retained.

The salamanders bridge the gap existing between the *Chologasters* and the blind members of the Amblyopsidæ. But even at the risk of monotonous repetition I want again to call attention to the fact that the salamanders do not belong to the same series as the Amblyopsidæ. The dioptric arrangements of *Typhlotriton* are all normal, the retina is normal in the young, but the rods and cones all disappear with the change from the larval to the adult condition. In *Typhlomolge*, the lens and largely the vitreous body are gone and the eye has collapsed. The vitreous body is, however, much better represented than in the blind Amblyopsidæ and the iris is, especially in the young, much better developed than in the fishes.

2. The retina.

(*a*) There is more variety in the degree of development of the pigment epithelium than in any other structure of the eye. Ritter has found that in *Typhlogobius* this "layer has actually increased in thickness concomitantly with the retardation in the development of the eye, or it is quite possible with the degeneration of this particular part of it. An increase of pigment is an incident to the gradual diminution in functional importance and structural completeness." There is so much variation in the thickness of this layer in various fishes that not much stress can be laid on the absolute or relative thickness of the pigment in any one species as an index of degeneration. While the pigment layer is relative to the rest of the retina, very thick in the species of *Chologaster* it is found that the pigment layer of *Chologaster* is actually not much, if any, thicker than that of *Zygonectes*; exception must be made for specimens of the extreme size in *papilliferus* and *agassizii*. In other words, primarily the pigment layer has retained its normal condition while the rest of the retina has been simplified and there may even be an increase in the thickness of the layer as one of its ontogenic modifications. Whether the greater thickness of the pigment in the old *Chologaster* is due to degeneration or the greater length of the cones in a twilight species, I am unable to say. In *Typhlichthys*, which is undoubtedly derived from a *Chologaster*-like ancestor, no pigment is developed. The layer retains its epithelial nature and remains apparently in its embryonic condition. It may be well to call attention here to the fact that the cones are very sparingly developed, if at all, in this species. In *Amblyopsis*, in which the degeneration of the retina has gone further but in which the cones are still well developed, the pigment layer is very highly developed, but not by any means uniformly so in different individuals. The pigment layer reaches its greatest point of reduction in *rosæ* where pigment is still developed, but the layer is fragmentary except over the distal part of the eye. We thus find a development of pigment with an imperfect layer in one case (*Troglichthys*) and a full developed layer without pigment in another (*Typhlichthys*). In the *Chologasters* the pigment is in part prismatic; in the other species granular.

(*b*) In the outer nuclear layer a complete series of steps is observable from the two-layered condition in *papilliferus* to the one-layered in *cornutus*, to the undefined layer in *Typhlichthys* and the merging of the nuclear in *Amblyopsis*, and their occasional total absence in *Troglichthys*. The rods disappear first, the cones long before their nuclei.

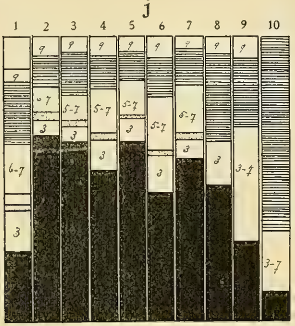

Diagram showing the per cents. of the total thickness of each of the layers of the retina in 1. *Zygonectes notatus*. 2. *Chologaster cornutus* 27 mm. long. 3. 43 mm. long. 4. *Chologaster papilliferus* 29–39 mm. and 5., 55 mm. long. 6. *Chologaster agassizii* 38 mm. long and 7., 62 mm. long. 8. *Amblyopsis*. 9. *Typhlichthys*. 10. *Troglichthys*.

(*c*) The outer reticular layer naturally meets with the same fate as the outer nuclear layer. It is well developed in *papilliferus*, evident in *C. cornutus*, developed in spots in *Typhlichthys*, and no longer distinguishable in other species.

(*d*) The layers of horizontal cells are represented in *papilliferus* by occasional cells; they are rarer in *cornutus* and beyond these have not been detected.

(*e*) The inner nuclear layer of bipolar and spongioblastic cells is well developed in *papilliferus*. In *cornutus* it is better developed in the young than in the older stages where it forms but a single layer of cells. There is evidently in this species an ontogenic simplification. In the remaining species it is, as mentioned above, merged with the outer nuclear layer into one layer which is occasionally absent in *Troglichthys*.

(*f*) The inner reticular layer is relatively better developed than any of the other layers and the conclusion naturally forces itself upon one that it must contain other elements besides fibers of the bipolar and ganglionic cells, for, in *Amblyopsis* and *Troglichthys*, where the latter are very limited or absent, this layer is still well developed. Horizontal cells in this layer have only been found in the species of *Chologaster*.

(*g*) In the ganglionic layer we find again a complete series of steps from the most perfect eye to the condition found in *Troglichthys*. In *papilliferus* the cells form a complete layer one cell deep except where the cells have given way to the optic fiber tracts which pass in among the cells instead of over them. In *cornutus* the cells have been so reduced in number that they are widely separated from each other. With the loss of the vitreous cavity the cells have been brought together again into a continuous layer in *Typhlichthys*, although there are much fewer cells than in *cornutus* even. The next step is the formation of a solid core of ganglionic cells and the final step the elimination of this central core in *Troglichthys*, leaving but a few cells over the anterior face of the retina.

(*h*) Müllerian nuclei are found in all but *Troglichthys*. In *C. cornutus* they lie in part in the inner reticular and the ganglionic layer. Cells of this sort are probably also found among the ganglionic cells of *Typhlichthys*.

3. The optic nerve shows a clear gradation from one end of the series of fishes to the other. In *Chologaster papilliferus* it reaches its maximum development. In *cornutus* which possesses an eye larger than *papilliferus*, but in which the ganglionic

layer is simplified, the nerve is measurably thinner. In *Typhlichthys* the nerve can be traced to the brain in specimens 40 mm. long, *i. e.*, in specimens which are evidently adult. In *Amblyopsis* the nerve can be followed to the brain in specimens 25 mm. long, but in the adult I have never been able to follow it to the brain. In *Troglichthys* it has become so intangible that I have not been able to trace it far beyond the eye.

We thus see that the simplification or reduction in the eye is not a horizontal process. The purely supporting structures like the scleral cartilages have been retained out of all proportion to the rest of the eye. The pigment layer has been both quantitatively and qualitatively differently affected in different species. There was primarily an increase in the thickness of this layer and later a tendency to total loss of pigment. The degeneration has been more uniformly progressive in all the layers within the pigment layer. The only possible exception being the inner recticular layer which probably owes its retention more to its supporting than to its nervous elements. Another exception is found in the cones, but their degree of development is evidently associated with the degree of development of the pigmented layer. As long as the cones are developed the pigmented layer is well developed or *vice versa*.

We find in general then that the reduction in size from the normal fish eye went hand in hand with the simplification of the retina. There was at first chiefly a reduction in the number of many times duplicated parts. Even after the condition in *Chologaster papilliferus* was reached, the degeneration in the histological condition of the elements did not keep pace with the reduction in number (*vide*, the eye of *cornutus*). The dioptric apparatus disappeared rather suddenly and the eye as a consequence, collapsed with equal suddenness in those members which, long ago, took up their abode in total darkness. The eye not only collapsed, but the number of elements decreased very much. The reduction was in the horizontally repeated elements. The vertical complexity, on which the function of the retina really depends, was not greatly modified at first.

In those species which took up their abode in total darkness the degeneration in the dioptric apparatus was out of proportion to the degeneration of the retina, while in those remaining above ground the retinal structures degenerated out of proportion to the changes in the dioptric apparatus, which, according to this view degenerates only under conditions of total disuse or total darkness which would necessitate total disuse. This view is upheld by the conditions found in *Typholgobius*, as Ritter's drawings and my own preparations show. In *Typholgobius* the eye is functional in the young and remains a light perceiving organ throughout life. The fish live under rocks between tide water (Eigenmann, 90). We have here an eye in a condition of partial use and the lens is not affected. The retina has, on the other hand, been horizontally reduced much more than in the Amblyopsidæ, so that should the lens disappear, and Ritter found one specimen in which it was gone, the type of eye found in *Troglichthys* would be reached without passing through a stage found in *Amblyopsis*, it would be simply a horizontal contracting of the retina, not a collapsing of the entire eye.

The question may with propriety be asked here, do these most degenerate eyes approach the condition of the pineal eye? It must be answered negatively.*

* The degree of degeneration reached in the eye of *Troglichthys* which began to degenerate comparatively recently would lead one to expect the pineal eye to be much more degenerate than it is actually found to be in the lizards unless its functions were something aside from light perception.

Ontogenic degeneration.

The simplification of the eye in *cornutus* with age has been mentioned in the foregoing paragraphs. The nuclear layers are thinner in the old than in the young. There is here not so much an elimination or destruction of elements as a simplification of the arrangements of parts, comparatively few being present to start with.

The steps in ontogenic degeneration can not yet be given with any degree of finality for *Amblyopsis* on account of the great variability of the eye in the adult. While the eyes of the very old have unquestionably degenerated, there is no means of determining what the exact condition of a given eye was at its prime. In the largest individual examined the eye was on one side a mere jumble of scarcely distinguishable cells, the pigment cells and scleral cartilages being the only things that would permit its recognition as an eye. On the other side, the degree of development was better. The scleral cartilages are not affected by the degenerative processes and are the only structures that are not. The fact that the eyes are undergoing ontogenic degeneration may be taken, as suggested by Kohl, that these eyes have not yet reached a condition of equilibrium with their environment or the demands made upon them by use. Furthermore, the result of the ontogenic degeneration is a type of structure below anything found in phylogeny. It is not so much a reduction of the individual parts as it is a wiping out of all parts.

PLAN AND PROCESS OF PHYLETIC DEGENERATION.

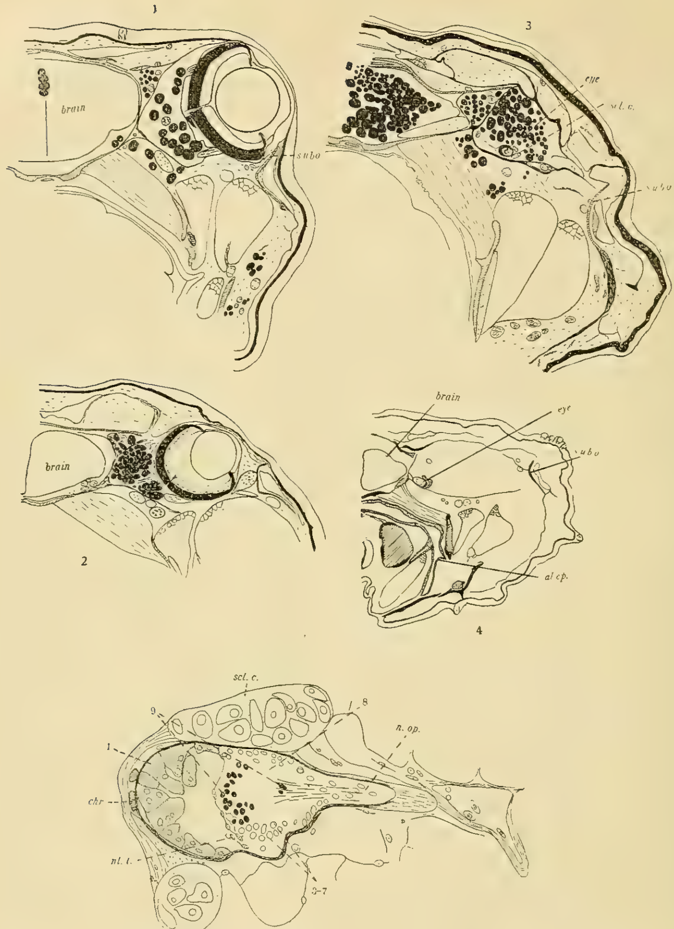
Does degeneration follow the reverse order of development, or does it follow new lines, and if so, what determines these lines?

Before discussing this point I should like to call attention to some of the processes of ontogenic development concerned in the development of the eye. There are three processes that are of importance in this connection: 1. The multiplication of cells. 2. The arrangement of cells including all the processes leading to morphogenesis. Frequently the first process continues after the second one has been in operation. 3. Lastly we have the growth and modification of the cells in their respective places to adapt them to the particular function they are to subserve—histogenesis.

Since the ontogenetic development of the eye is supposed to follow in general lines its phylogenetic development the question resolves itself into whether or not the eye is arrested at a certain stage of its development and whether this causes certain organs to be cut off from development altogether. In this sense the question has been answered in the affirmative by Kohl. Ritter, while unable to come to a definite conclusion, notes the fact that in one individual of *Typhlogobius* the lens, which is phylogenetically a new structure, had disappeared. But this lens had probably been removed as the result of degeneration rather than through the lack of development.

Kohl supposes that in animals placed in a condition where light was shut off, more or less, some of the developmental processes are retarded. In successive generations earlier and earlier processes in the development of the eye are retarded and finally brought to a standstill; thus every succeeding generation developed the eye less. Total absence of light must finally prevent the entire *anlage* of the eye, but time, he thinks, has not been long enough to accomplish this in any vertebrate. The cessation of development does not take place at the same time in all parts of the eye. The less important, those parts not essential to the perception of light, are disturbed first. The retina and the optic nerve are the least affected, the iris comes next in the series. Because the cornea, aqueous and vitreous bodies and the lens are not essential for the performance of the function of the eye, these structures cease to develop early. The processes of degeneration follow the same rate. Degeneration is brought about by the falling apart of the elements as the result of the introduction of connective tissue cells that act as wedges. Abnormal degeneration sometimes becomes manifest through the cessation of the reduction of parts that normally decrease in size (p. 269), so that these parts in the degenerate organ are unusually large.

Kohl's theoretical explanation is based on the study of an extensive series of degenerate eyes. He has not been able to test the theory in a series of animals actually living in the condition he supposes for them, and has permitted his erroneous interpretation of the highly degenerate eye of *Troglichthys* to lead him to the theory of the arresting of the eye in ever-earlier stages of ontogeny. The eye of *Troglichthys* is in an entirely different condition from that supposed by him. The mere checking of the normal morphogenic development has done absolutely nothing to bring about this condition and it could not have been produced by the checking of development in ever earlier and earlier stages of ontogeny, for there is no stage in normal ontogeny resembling in the remotest degree the eye of the adult *Troglichthys*. The process of degeneration as seen in the Amblyopsidæ is in the first instance one of growing smaller and simpler (not more primitive) in the light—not a cutting off of late stages in the development in the dark. The simplified condition, it is true, appears earlier and earlier in ontogeny till it appears along the entire line of development, even in the earliest stages. This simplified condition never gives any evidence of being more primitive; it is simply less elaborate. The tendency for characters added or modified at the end of ontogeny to appear earlier and earlier in the ontogeny is well known, and there is no inherent reason why an organ disappearing in the adult should not eventually disappear entirely from ontogeny. The fact that organs which have disappeared in the adult, have in many instances not also disappeared in the ontogeny and remain as so-called rudimentary organs has received an explanation from Sedgwick. In his re-examination of the biogenetic law he came to the conclusion that "the only functionless ancestral structures, which are present in development, are those which at some time or another have been of use to the organism during its development after they have ceased to be so in the adult." The length of time in such cases since the disuse of such an organ in the young is much shorter than that since its use in the adult. All organs functionless in the adult, but functional in the early ontogeny, develop in the normal way. Organs no longer functional at any time dwindle all along the line of development. In *Typhlogobius*, where the eye is functional in the young, it develops to full size in the embryo and it is not till late in life that degeneration is noticeable. In *Amblyopsis* on the other hand, where the eye has not been functional at any period of ontogeny for many generations where the eye of both the young and adult lost their function on entering the caves, and where degeneration begins at an early period and continues till death, the degenerate condition has reached the early stages of the embryo. It is only during the first few hours that the eye gives promise of becoming anything more than it eventually does become. The degree of degeneration of an organ can be measured as readily by the stage in ontogeny when the degeneration becomes noticeable as by the structure in the adult. The greater the degeneration the further back in the ontogeny the degenerate condition becomes apparent unless, as stated above, the organ is of use at some time in ontogeny. It is evident that an organ in the process of being perfected by



1. Part of the section of the head of *Chologaster papilliferus* at the optic nerve; subo.-suborbital.

2. Part of the section of the head of *Chologaster agassizii*.

3. Part of the section of the head of an *Amblyopsis* showing the location of the eye; subo.-suborbital. scl., scleral-cartilage.

4. Part of the section of the head of *Troglichthys* passing through the eye; al. ep., alimentary epithelium.

5. The most degenerate vertebrate eye known, that of *Troglichthys* in vertical section. 1, pigment layer of the retina; 3–7, retina from the pigmented layer to the inner reticular layer; 8, inner reticular layer; 9, ganglionic layer; n. op., optic nerve; nl. l., nuclei of the hyaloid; chr. choroid pigment; scl. c., scleral cartilages.

selection may be crowded into the early stages of ontogeny by post selection. Evidently the degenerate condition is not crowded back for the same reason. How it is crowded back I am unable to say. A satisfactory explanation of this will also be a satisfactory explanation of the process by which individually acquired characteristics are enabled to appear in the next generation. The facts, which are patent, have been formulated by Hyatt in his law of tachygenesis.

Cessation of development takes place only in so far as the number of cells are concerned. The number of cell generations produced, being continually smaller, result in an organ as a consequence also smaller. In this sense we have a cessation of development (cell division, not morphogenic development) in ever earlier stages. That there is an actual retardation of development is evident from *Amblyopsis* and *Typhlichthys* in which the eye has not reached its final form when the fish are 25 mm. long.

Histogenic development is a prolonged process and ontogenic degeneration is still operative at least in *Amblyopsis*.

Degeneration in the individual is not the result of the ingrowth of connective tissue cells as far as I can determine. It is rather a process of starving, or shriveling and resorption of parts.

From the foregoing it is evident that degeneration has not proceeded in the reverse order of development, rather the older normal stages of ontogenic development have been modified into the more recent phyletic stages through which the eye has passed. The adult degenerate eye is not an arrested ontogenic stage of development but a new adaptation and there is an attempt in ontogeny to reach the degenerate adult condition in the most direct way possible.

CARL H. EIGENMANN.

SCIENTIFIC BOOKS.

The Ore Deposits of the United States and Canada. By JAMES FURMAN KEMP. Third Edition entirely rewritten and enlarged. New York and London, The Scientific Publishing Company. 1900.

The first edition of 'Kemp's Ore Deposits of the United States' appeared in 1893. The second edition from the same plates, in which forty to fifty pages of additional matter had been inserted, was published in 1895. We now have the third edition, with entirely new plates, which forms a volume nearly twice as thick as the first, with larger type, heavier paper and additional plates which contribute, as well as the new matter, to its increased size. As this is practically the only modern work dealing in any adequate fashion with this important subject, and as it hence constitutes the standard work for reference with regard to the ore deposits of the United States and Canada, it is important to consider its shortcomings as well as its merits, and even to dwell upon the former.

It must be evident to all who consult the work that Professor Kemp has been remarkably thorough in his search of the literature of his subject and few books have a more complete bibliography; the references, moreover, are distributed throughout the text, not lumped together at the end, so that it requires very little labor on the part of the reader to go back to original authorities on any given point. Kemp possesses, moreover, in a high degree the important faculty of reading intelligently and of expressing concisely the leading facts gathered in the course of his reading. This is perhaps the most important qualification for a work that is essentially a compilation rather than an original treatise.

For a philosophical treatment of phenomena like ore deposits, in which different observers may in all honesty draw diametrically different conclusions from their respective examinations of the same deposit, it is essential that the author should have been able by personal inspection to verify the relative accuracy or degree of probability of opposing views; for in this case, even if we may differ with the author's theoretical opinions, we know that the coefficient of error, if such we regard it, will be constant through his work.

In the first edition of Kemp's work, there was some evidence of haste in preparation, for which, apparently, the publishers' demand for copy was in a measure responsible. In the later editions, there has been ample time to remedy any shortcomings that may have arisen from this cause, hence it is well to examine with some detail the nature of the changes that have been made in the last edition. The book is divided into two parts; Part II., a description of the deposits of the respective metals, occupying about five-sixths of the total space. In Part I., which deals with general characteristics, there has been added to Chapter I., on the 'Formation of Cavities,' a statement of Van Hise's division of the earth's crust into three zones, one of fracture, one of fracture and flowage combined, and one of flowage alone; also six pages on 'Underground Circulation,' but nothing to the very brief mention of 'Replacement as a mode of deposition.' In Chapter III., on 'Minerals and their source,' there has been added a paragraph on the association of certain metals with certain rocks, and one on secondary migrations of vein materials, with references to De Launay's recently expressed views. In Chapter VI., on the 'Classification of Ore Deposit,' the author has elaborated the discussion of his own system; especially in the direction of magmatic differentiation, relegating the descriptions of other systems to an appendix at the close of the work; the other three chapters are practically unchanged.

It is in the descriptions in Part II. that the most changes have been made, and these have been mainly as insertions of new paragraphs, so that the statement on the title page that the volume has been 'entirely rewritten,' for which the publishers are evidently responsible, is hardly justified. The actual increase in the number of pages is one hundred and eleven, but this is in considerable part due to larger type. It has evidently been considered important to preserve, as far as possible, the same relative numbering of paragraphs in this as in former editions; new matter is largely taken from new publications of Government surveys, and from papers in the transactions of the American Institute of Mining Engineers. The following are the more important changes in order of chapters:

In descriptions of 'Iron Deposits' important enlargements are made from the work of Van Hise and his associates in the Lake Superior region and from the author's studies in the Adirondacks. Under 'Copper Ores' the description of the Ducktown and Butte deposits have been largely rewritten, and those on the 'Lake Superior Deposits' have been elaborated; mention is made of some in Idaho. Additions have been made to the discussions of the Lead and Zinc Deposits of the Mississippi Valley from the reports of Winslow and Jenney; in the chapter on 'Zinc alone,' no change is perceptible. Under 'Lead and Silver' new descriptions are given of the Tenmile, Eagle River and Aspen districts in Colorado (the latter rather inadequate), and under 'Silver and Gold' of the Telluride, Custer County and Cripple Creek districts, in the same State. Under the same head, hitherto unpublished data is given from a paper by J. D. Irving on the Black Hills' Deposits, which, like those of Cripple Creek, are more properly classed under 'Gold alone.' New data as to Montana, Idaho and Utah, are added on the authority of Weed, Lindgren and Spurr, respectively. Descriptions of the 'Gold Deposits of the Pacific Slope' are very largely rewritten from the reports of Lindgren, Becker, Turner and others. Under the heading 'Gold elsewhere in the United States and Canada,' the gold deposits of the Appalachians, which have been barely noticed before, are briefly described, mainly from Becker's report; but of the eight pages of text fully one-half are occupied by references. Eleven pages are given to Alaska and British Columbia, with notes on Nova Scotia. About eighteen paragraphs have been added to the chapter on the 'Lesser Metals' in which those that bear upon the theory of magmatic separation are especially prominent.

The improvement in the illustrations of the volume is most marked, as there were very inferior reproductions in former editions; some of the poorest have been eliminated, and the half-tone prints, both old and new, are of remarkably improved quality, though some still leave much to be desired (*e. g.*, Fig. 122). The new illustrations are largely from Government reports, but many photographs are by individuals, especially by the author. From these it appears that, since the publication of the first edition, the author has himself visited some of the important mining districts of the west, but in many cases it is evident he still does not possess sufficient familiarity with the regions to judge, from published reports of a given mining district, whether or not those of one author possess inherent merits entitling his views to superior consideration over those of another.

Professor Kemp, who is an excellent petrographer, has, as shown by his papers published elsewhere, a decided leaning toward the theory of magmatic separation of ore minerals held by Scandinavian geologists, like them, viewing the subject primarily from a petrographic standpoint. The sufficiency of this method for the formation of ore deposits, unless aided by later concentrations through the agency of circulating waters, is not, however, regarded with so much favor by most mining geologists of wide practical experience in America.

Taken as a whole the book presents an excellent bird's-eye view of the ore deposits of the country, as nearly up to date as is practicable, with a fair-minded presentation of the various views held as to their origin and mode of formation. The mining community is certainly indebted to Professor Kemp for the ability and thoroughness with which he has accomplished his laborious task, the magnitude of which few beside the author can adequately appreciate.

S. F. EMMONS.

The Nature and Work of Plants. An Introduction to the Study of Botany. By DANIEL TREMBLY MACDOUGAL, Ph.D., Director of the Laboratories, New York Botanical Garden. New York, The Macmillan Company. 1900. Pp. xviii + 218. 12mo.

The author's introductory paragraph gives us his point of view. "The course outlined in this little book is essentially a study of the functions or action of the plant, and organs are considered chiefly as instruments for the performance of work, with but little attention to their morphology. It is believed that this method of introduction to the subject of botany will be best suited for beginners who have not at hand the facilities of a laboratory. In conformity with this idea, the use of technical terms has been restricted to the actual necessities of logical treatment, and the demonstrations have been developed by the simplest experimental methods."

He takes up the subject in ten chapters, as follows: I. the composition and purposes of plants: II. the material of which plants are made up; III. the manner in which different kinds of work are divided among the members of the body; IV. the roots; V. the leaves; VI. stems; VII. the way in which new plants arise; VIII. seeds and fruits; IX. the power or energy of the plant; X. relations of plants to each other, and the place in which they live. These chapters include two hundred and fifty paragraphs, each of which directs attention to a single fact or group of facts, which in most cases may be subjected to observation or experiment by the pupil. Very simple suggestions are given for these observations and experiments, and the pupil is usually left quite free to use his own ingenuity in carrying them out. While function is emphasized, structure is not ignored, but this is almost entirely confined to gross structure, the author's intention being to require no greater aid to the naked eye than a hand lens magnifying from six to ten diameters.

The book is non-technical, in conformity to the trend of recent text-books, and is remarkable in having *no illustrations whatever*, the author depending upon the simplicity and clearness of his text and the plant or experiment itself to furnish ideas to the pupil. Whether the pupils and teachers who have been brought to expect fine 'half-tone' illustrations of everything from cell elements to plant communities, and a profusion of diagrams of physiological apparatus, with 'half-tones' showing the results of experiments, will take kindly to this book which implies and demands *work* on the part of both, remains to be seen. There is a good deal of laziness in the world, and we fear that the temptation to use a book with pictures (which too often are studied in lieu of the experiments) may be so strong as to prevent the general use of Dr. MacDougal's book.

CHARLES E. BESSEY.
THE UNIVERSITY OF NEBRASKA.

De praktische toepassing van Stoomschuif- en Schaarbewegingen bij Stationaire, Locomobiel-, Locomotief- en Scheeps-machines door C. STEUERWALD; Mit eene voorede van H. A. RAVENEK. By W. S. AUCHINCLOSS. Leiden. A. W. Sijthoff. 1899. Pp. 108. Many illustrations.

This book is a translation, into the Dutch, of Auchincloss' well-known treatise on valve-motion, of which a German version has long been in type. The translator is a member of the Faculty of the Polytechnic School of Delft; the introduction is written by Professor Ravenek of the same institution. There is no lack of such works in the English, German and French languages; but the work of Auchincloss excels in the simple and very clear manner in which the graphical constructions are made, "without preceding calculations, simply by outlines on the drawing-board," as Professor Ravenek says in his introduction. The treatise is adjudged 'very suitable to be placed in the hands of apprentices and draughtsmen' as well as of students in mechanical engineering.

The British measures of the original are replaced in the translation by metric.

This reproduction of the American work in Dutch is one of the most gratifying testimonials to the value of the work which has yet appeared. The book is unusually well-printed and its illustrations are exceptionally well-made.

R. H. T.

Mesure des température élevées. Par. H. LE CHATELIER et O. BOUDOUARD. Paris, G. Carré et C. Naud. 1900. Pp. 1–220.

In these few pages Le Chatelier and his assistant have given a terse and useful account of the principal methods of cotemporaneous pyrometry. Measurement of high temperature has, as a rule, referred to the comparison of different temperature functions, and the results obtained have therefore differed enormously. The confusion has gradually subsided however, in proportion as the air thermometry of high temperatures has been more fully mastered. Le Chatelier makes a judicious selection of standard temperatures in the introductory chapters of his book and estimates the probable error to be 1° between 200° and 500°, 5° between 500° and 800°, 10° between 800° and 1100° and upwards 50° above 1100°. In the list of pyrometers which follows I should have referred the calorimetric pyrometer to Pouillet and perhaps included the viscosity pyrometer.

The brief account given of normal temperatures as defined by Kelvin and their relation to the air thermometer is intelligible, well digested and practical in character, though these corrections at high temperatures are of small moment. An account is also given of the standard (hydrogen) air thermometer of the Bureau International at Sèvres, which may be taken as a preliminary model, since the normal air thermometer for high temperatures has not yet been constructed. The authors might have added that very definite steps are being taken in this direction by Holborn and Day at the Reichsanstalt. It has been shown that the platinum-iridium alloy is impervious to nitrogen rigid up to the highest industrial temperatures. Nothing now stands in the way to prevent high temperature measurements from attaining the full precision of low temperature measurements.

The errors usually encountered in high temperature thermometry make up Chapter III. of the book, after which various historical pyrometers are described from figures, and critically discussed. It is interesting to note that the errors of Pouillet were largely due to the high value of the coefficient of expansion then in vogue. Among the whole series the interferential pyrometer of D. Berthelot may be singled out as being peculiarly promising, both on account of the simple and apparently correct principle on which it is based, and on account of its indefinitely high temperature limit of application.

In preference to platinum which is expensive and iron which behaves anomalously, nickel has been recently proposed for calorimetric pyrometry. The authors give a series of appropriate data, and figures of available apparatus, together with the probable inaccuracies of this somewhat unsatisfactory method of pyrometry. Incidentally it may be appropriate (as for instance in the case of Violle's famous experiments) but it now has little general laboratory value.

The resistance pyrometer, introduced by Siemans and perfected by Callendar and Griffiths, is for shorter ranges of high temperature (0°–1000°) now without a rival in accuracy. It has the additional advantage of continuous registry almost as far down as the absolute zero of temperature. Calibrated with reference to Callendar's equations by aid of the specially determined boiling point of sulphur (an error was detected in Regnault's value by this very instrument), it is also a convenient instrument in practice.

The chapter on thermoelectric pyrometry, in which Le Chatelier is specially interested is naturally very full, at least in relation to the D'Arsonval method of measurement. This is obviously the more practical though the zero methods give a permanent record. Figures are abundantly inserted of the galvanometers, furnaces, crucibles, and the other necessary paraphernalia of the pyrometric laboratory.

The chapter on radiation pyrometry is antiquated and meagre, inasmuch as nothing is said about the remarkable results of Wien, Lummer, Kurlbaum, not to mention Planck and others who are remodeling the whole subject. So also the mention made of the bolometer is altogether inadequate. On the other hand Le Chatelier enters at length into photometric radiation pyrometry which is of secondary interest by comparison.

The final chapters contain interesting information on Wedgewood pyrometry and on Seeger cones, recipes being given in detail. The book closes with the remarkable work which Roberts-Austen is now doing with his self-registering pyrometer and the new differential method of observation.

The book as a whole is obviously an outgrowth of the laboratory and is supplemented by personal observation. As such it needs no further recommendation.

C. BARUS.

BROWN UNIVERSITY,
PROVIDENCE, R. I.

SOCIETIES AND ACADEMIES.

GEOLOGICAL SOCIETY OF WASHINGTON.

THE 99th regular meeting was held at the Cosmos Club, March 14, 1900.

Under informal communications, Mr. J. A. Taff exhibited some asphalts from Indian Territory, and briefly described their occurrence.

On the regular program the following papers were presented:

(1) 'Glacial Sculpture in the Bighorn Mountains,' by Mr. F. E. Matthes.

The glacial cirques on the Bighorn Range are exceptionally well preserved and complete in outline. The crests and spurs separating them have remained unglaciated, and are remnants of pre-glacial topography. The cirques do not necessarily develop at the heads of the pre-glacial alpine valleys. In numerous cases the upper ends of the latter have remained unglaciated while cirques have formed lower down. This raises the question: What are the conditions necessary for the formation of a cirque; or, since a cirque is essentially the product of frost-action in the bergschrund, what determines the location of the bergschrund?

It was shown that the unglaciated areas above the bergschrunds were covered by *quiescent névé* during the period of glaciation. They were *nivated.* The effects of *nivation* are the accentuation of abrupt slopes and the effacing of the pre-glacial drainage lines by deposits of powdered rock produced by frost-fracturing along the edges of the névé sheets. The bergschrunds constitute the boundary between the *nivated* and *glaciated* areas.

According to the evidences gathered in the Bighorn Mountains the location of the boundary line is intimately connected with the depth of the valleys, or, more strictly, with the depth of the névé. That the spheroid of the mean annual temperature of 32° F. does not influence its location is demonstrated by the fact that cirques and nivated areas exist side by side at all elevations from 10,000 feet up to 13,000 feet.

The conclusion is that névé may remain stationary or acquire motion at any of these elevations, regardless of the altitude of the spheroid of 32° F. The only factor which determines whether a body of névé shall have motion or not is its depth.

(2) 'Physiography of the Arkansas Valley Region,' by Mr. Geo. I. Adams.

This is essentially a gradation plain, below which lie the present stream valleys, and above which rise numerous residual hills, ridges, mesas and mountains, to elevations usually not greater than 200 feet. The mountains which occupy the broader synclines, however, may rise from 1500 to 2300 feet above sea-level. The rocks have been thrown into open folds, with east and west trend. There is little faulting. The northern limit of the region is the Boston Mountains, having a monoclinal structure and forming the southern edge of the Ozark Plateau. To the south it is limited by the closely folded and faulted structure of the Ouachita Mountains.

The Arkansas Valley Region may be considered as an extension of the Prairie Plains eastward through the mountains of Indian Territory and Arkansas to the Gulf Plains. It shows evidence of an earlier erosion period in which the streams flowed at relatively higher levels. It may be compared with the Appalachian Valley region in its structural and physiographical relations.

David White,
Secretaries.

BIOLOGICAL SOCIETY OF WASHINGTON.

The 320th meeting, held on Saturday, March 10th, was devoted to an address by Dean C. Worcester on 'The Birds and Mammals of the Philippines' which was illustrated by lantern slides. The speaker dwelt particularly upon the distribution of the birds, showing the part played by deep straits as barriers to migration between the islands, and stating that the Bornean aspect of the fauna was confined to Palawan and the adjacent small islands. The difficulties of collecting in the Philippines were described, but it was pointed out that these islands offer exceptional opportunities for the zoologist and that a careful study of the fauna might be expected to throw much light on the problems of specific and individual variation.

F. A. Lucas.

NEW YORK ACADEMY OF SCIENCES.

SECTION OF ANTHROPOLOGY AND PSYCHOLOGY.

The regular meeting of the Section was held on Friday, February 23d. The first paper of the evening, entited 'Symbolism of the Huichol Indians,' was presented by Carl Lumholtz. The Huichols are a small tribe of about 4000 souls living in the southwestern part of Mexico, on a spur of the Sierra Madre. Their country being difficult of access, they have been left comparatively untouched by civilization, and thus preserved their ancient beliefs and customs intact to the present day. The paraphernalia of the warrior of ancient times, *i. e.*, of the gods of the present race, furnish the principal symbolic objects by which prayers are expressed, and the most important of these articles is the ceremonial arrow left as a sacrificial offering in the temples and considered a carrier of prayers. It is painted and otherwise decorated with symbolic emblems, and attached to it are representations of other paraphernalia of the warrior, as the front-shield and the back-shield, the latter being also viewed as the mat or bed of the god. Frequently the object of the prayer is incorporated in an attachment to the arrow. The vivid imagination of the people makes them see analogies in the most heterogeneous phenomena. They see serpents in the sky, the clouds moving through space, the wind sweeping over the fields, the rain falling down, even in their girdles and ribbons. Certain insects which appear during the wet season are identical with corn, and corn is identical with hikuli, and hikuli identical with deer. The same tendency to consider heterogeneous objects as identical may be observed in the fact that a great variety of objects are considered as plumes. Clouds, cotton-wool, the white tail of the deer, the deer's antlers, and even the deer itself are plumes, and the serpents are believed to have plumes. Naturally, much ambiguity is found, and there are few symbols that express always the same meaning; nor is an idea always expressed by the same symbol. Although this gives a certain individuality to the symbolic objects, we can always trace the connection between the thought to be expressed and the symbol expressing it. The second paper on 'Symbolism of the Arapahoe Indians' was read by A. L. Kroeber. It was shown with the aid of lantern slides that the decorative art of the Arapahoe Indians is throughout realistic (*i. e.*, pictorial) or symbolic.

Geometric patterns occur, but rarely, and the general character of the art is suggestive rather of pictography. Symbols representing animal life, physical nature, and abstract ideas predominate.

Dr. Franz Boas presented a paper on 'The Growth of Children.' A series of measurements of children repeated at annual intervals proves that the variations of growth must be interpreted as mainly due to acceleration and retardation of growth, combined with hereditary influences, which determine the amount of annual growth. It was shown that it is possible to determine the essential elements which determine the amount of annual growth by admission of regulated measurements. These result in a determination of (1) the relation between final development and development at any given period; (2) the typical development at a given period; and (3) the variability of the series in regard to period.

CHARLES H. JUDD,
Secretary.

ZOOLOGICAL CLUB, UNIVERSITY OF CHICAGO.

AT the meeting of January 10th, Mr. R. H. Johnson presented a paper prepared in collaboration with Mr. R. W. Hall, entitled 'Variation in *Palaemonetes* correlated with Salinity.' After calling attention to the fact that our marine species of *Palaemonetes* differ from the fresh-water form in presenting a greater number of rostral teeth, Mr. Johnson stated that various lots of the marine species which were collected in brackish water show an intermediate condition as regards the rostral teeth. A complete series of intermediate forms exists and the natural inference is that the different degrees of salinity cause the observed differences in form. The experiment of rearing the animals in media of different degrees of salinity has not yet been made by the authors, but will be attempted, as this alone will afford complete evidence in regard to the matter.

The second paper of the meeting was a review by Mr. A. N. Young of several recent papers, by Edmond Bordage, on regeneration in insects.

The second meeting of the month was held on January 31st. The first paper of the session 'A Review of Bresslau's paper on the Develment of the Rhabdocoels,' was presented by Mr. E. H. Harper.

The remainder of the session was occupied by an exhibition of a very interesting series of the extremely variable land snail *Pyramidula strigosa* Gould, collected by Hemphill from the Great Basin, a loan from the Powell Museum of the Illinois Wesleyan University through the kindness of Professor J. C. Hartzell. Attention was called to the direction taken by some of the variations. The recorded localities seem to indicate that some of the varieties are quite local in their distribution and that there is distinct geographical isolation. It was suggested that the history of the topography might throw light upon this isolation. Gilbert's map of 'Lake Bonneville' shows that the Oquirrh Mountains (the locality for the *Oquirrhensis* and *Utahensis*) were then situated upon a narrow peninsula. Climate may have since aided in preserving this isolation. This species is of special interest to students of evolution and well deserves to be better and more widely known.

C. M. CHILD.

THE ACADEMY OF SCIENCE OF ST. LOUIS.

AT the meeting of the Academy of Science of St. Louis on the evening of February 19, 1900, 43 persons were present. Professor Patrick Geddes, of University College, Dundee, in an address of about an hour, traced the increasingly complex relation of the world to science and the rapidly increasing need of co-ordination of the sciences, and then gave a concise account of the purposes which it is hoped to realize and the methods to be adopted by the International Association for the Advancement of Science, Art and Education, which grew out of the meetings of the British and French Associations for the Advancement of Science last autumn, and is to hold its first international assembly at the Paris Exposition in the course of the present year, the purpose of the Association, recognizing the wealth of instructive material brought together by the great transient museums, the World's Fairs, being the fullest possible utilization of the educational facilities so brought together.

On the conclusion of Professor Geddes' address, Hon. D. R. Francis, on the call of the President, spoke briefly on the subject presented by Professor Geddes, expressing a warm interest in the work of the Association, the coöperation of which with the Louisiana Purchase Exposition being planned for St. Louis, a few years hence, is hoped for.

A paper by Dr. G. A. Miller, 'On the primitive substitution groups of degree ten,' was presented by title.

Professor J. L. Van Ornum, late of the United States Engineer Corps, spoke interestingly on 'The sanitary cleaning of a city, as exemplified by Cienfuegos, Cuba,' explaining the conditions found by the United States Army on taking possession of that city, and the thoroughness with which the streets, court yards and cesspools were cleansed by the Engineer Corps, which also charged itself with the betterment of the city water supply. A diagram which the speaker had prepared showed that in addition to a very marked lowering of the death rate which attended the supply of an abundance of wholesome food, on the occupation of Cienfuegos, there had been a decrease of considerably over fifty per cent. in the weekly death rate, directly attributable to the sanitary cleansing of the city; and he further stated that since this work had been done, yellow fever, which before that time had been endemic in Cienfuegos, had been absent from the city.

Five persons were elected to active membership in the Academy.

William Trelease,
Recording Secretary.

DISCUSSION AND CORRESPONDENCE.

'FLOATING SAND.' 'FLOATING STONES.'

In the *American Geologist* for January, 1896 (Vol. XVII, pp. 29–37) I published an article on 'Floating Sand: an Unusual Mode of River Transportation' in which I gave a detailed account of that phenomenon as seen by me during the preceding August on the Llano river, a tributary of the Colorado, at Bessemer, a station on the Austin and Northwestern Railroad, 94 miles from Austin, Texas. I further gave an account of numerous experiments performed for the purpose of ascertaining how sand may be floated, what sand will float, and why sand will float. No less than fourteen different sands were examined some of which were from widely separated localities, as, for instance, the coast of Long Island and that of Lake Michigan, at Chicago; from the friable sandstone at Alum Bay, Isle of Wight, and the Lower Carboniferous at Pea Ridge, Arkansas. At the time of writing, I may add, the only account of floating sand known to me was in a brief article 'On a Peculiar Method of Sand-Transportation by Rivers' published by Mr. James C. Graham in the *American Journal of Science*, III, Vol. XL, p. 470 (December, 1890) and this I had failed to notice until I had begun my investigations.

Without going into the details of my paper further at this point, I will enumerate the conclusions reached which were as follows:

"1. That sand grains will float in perfectly still water for an indefinite time.

"2. That the grains which float are not necessarily siliceous. That flakes of mica, fragments of marble, bituminous shale, etc., also float and that some of them, the marble and the bituminous shale, for example, are unusually buoyant.

"3. That the property of floating is not confined to the sand of any particular locality, but depends to a considerable extent upon the angularity, *i. e.*, the shape of the grains.

"4. That whether sand will float or not depends, also, upon the mode of launching. Whether it be by ripple waves, as stated by Mr. Graham, or by undermining, it must be gently done, for should the grains be plunged into the water with sufficient force to completely immerse them they will immediately sink.

"5. That the natural conditions necessary to the floating of sand in rivers are somewhat unusual, depending, in the case of the Llano, upon a flood without local rains and, in that of the Connecticut, upon the manner in which certain waves strike a sand-bar. It is quite possible, however, that floating sand is much more common than is ordinarily supposed.

"6. That the physical explanation of the problem is complex rather than simple, and at best unsatisfactory in several important particulars, and that with the advance of molecular physics we may hope for a better understanding of what we now, for convenience, term 'superficial viscosity' and 'capillary attraction.'"

This article attracted considerable attention and was reprinted entire or in part in other journals.

Among the letters received at the time of publication, the following substantiate the last part of the 5th conclusion, viz, that floating sand is much more common than is ordinarily supposed:

Professor William Morris Davis wrote, January 28, 1896: "I have noticed the same thing (floating sand) on the tidal currents of Cape Cod."

Mr. Henry W. Nichols of Field Columbian Museum, Chicago, wrote, February 3, 1896:

"I would like to add another instance. At Cohasset, Mass., a town about twenty-five miles south of Boston, there is a land locked inlet from the sea, known as Little Harbor. There are here and there along its shores, small beaches of angular gravel and sand. When there is no wind, the tide rises gently on these beaches without even a ripple, and gently lifts grains of dry sand which form such patches as you describe a foot or more in diameter. Some days such floating patches are very numerous, and may be seen going out with the tide all the way from the head of the Harbor to the outlet over a mile distant. The rock of the region is granite and the sand is probably derived from it. The grains are very angular. Without thinking much upon the subject, I have always considered that a film of air adhered to the grains and kept them from wetting, and that the floating was due to surface tension as in the case of the familiar experiment with a needle."

In the *American Geologist* for November, 1898, Professor George E. Ladd discussed the 'Geological Phenomena resulting from the Surface Tension of Water.' Under the caption 'Floating Materials' (p. 283) he says:

"It is not uncommon to see materials of a higher specific gravity than water floating upon its surface.

"The principle involved is again that of surface tension, and substances thus float only when the attraction for the water is less than the latter's surface tension.

"The geological results of this principle are chiefly the floating and shifting from place to place of sands. While I have observed such an occurrence on many occasions, in different places, the most important noticed was in Massachusetts, at the mouth of the Merrimac River. Here the northern end of Plum Island, which is a vast accumulation of sand, shuts in the harbor of Newburyport on the southeastern side. The action of the winds, of the waves, in time of storm, and the shifting currents (the position of the harbor's channel varying rapidly) result in the formation of numerous bays or 'basins' in the sandy island, on the protected side, often occupying extensive areas. The largest of these, having a circumference of something over a mile, has endured for the past forty or fifty years. The sand consists mainly of coarse, sharply angular quartz, but much feldspar is present, some mica, and numerous fragments of schistose and gneissic rocks. Whenever, on the retreat of the tide, the beaches and the exposed bars are dried by the sun's heat, the returning water, if not too greatly disturbed by unfavorable winds, lifts, as it creeps up the slope, the whole superficial film of sand, including large thin pebbles of schist, and floats it gently on the surface. The surface of the water, near the shores bearing the sand, commonly moves out towards the main river, even when the tide is rising, the incoming water flowing beneath.

"I have estimated that in the course of a year something like a thousand tons of sand, at a minimum, are lifted and borne away to new resting places by the floating power of surface tension at this locality alone."

During the present year Dr. Erland Nordenskiold's communication to *Nature* (January 18, 1900, p. 278) on 'Floating Stones,' seen by him during his recent visit to southwest Patagonia, has evidently been read with great interest in England and has been the means of calling forth a number of statements concerning floating sand and other mineral matter, such as fragments of shells. Neither Dr. Nordenskiold nor the other correspondents seem to have been aware of the papers published on that subject by Messrs. Graham, Ladd and myself, though printed in journals of wide reputation and extended circulation. Dr. Nordenskiold says:

"Whilst rowing in the long and narrow channel of Ultima Esperansa, to study the plankton, we observed, when the sea was calm or only agitated by a slight swell, small fragments of slate which floated upon the surface packed together in larger or smaller clusters. They drove hither and thither in the neighborhood of the shore, until they were driven away by the strong current which at intervals swept forward in the channel. The quantity was considerable; for instance, 700 of them were obtained at one cast of the net in a few minutes. The stones had evidently drifted out from the beach, which consisted mainly of similiar stone fragments washed off from the cliffs composed of a bituminous mesozoic slate. The surface of the stones was dry, and they sunk immediately when it became wet by touching or by the movement of the swell.

"The slate fragments collected on the sea surface had a specific gravity of 2.71. The specific gravity of the water in the channel was only 1.0049 at a temperature of 15° C. (59° F.). The largest stone which I obtained from the surface weighed 0.8 gram. Twenty of the smaller fragments had a mean weight of 0.3 gram. The fragments contained no air cavities perceptible to the unaided eye."

These stones, which are pictured in *Nature*, are, it must be confessed, extraordinarily large. The specific gravity of the Llano sand was 2.59 and the largest grains could not approach the stones above mentioned in size.

To quote further from Nordenskiold:

"On examining the floating stones one could discern small gaseous bubbles attached to the under surface of them, and at the shore stones can be seen on the very fringe of the beach which are just beginning to float lightened by gaseous bubbles."

In my paper (p. 31) a possible explanation is offered for the presence of the 'gaseous bubbles': In one of my experiments I dug several holes in the sand forming a bank in the bed of the Llano and when their sides caved in, the dry grains forming the outer coat of the deposit, were gently launched and floated much more abundantly than in a previous experiment when the surface was damp. Furthermore, as each mass of sand slipped into the water, and exclusive of the floating grains, sunk, *the air contained in the interstices between the particles rose to the surface forming a patch of foam or froth.*

Again Dr. Nordenskiold remarks:

"It is probable that the stones were not only provided with gas bubbles, which can be perceived by the eye, but that they were surrounded by an envelope of gas supported by an insignificant coating of algæ, of which the stones are surrounded. At least, traces of diatoms and algæ are discernible on the stones after drying. The greasy surface of the mineral of which the stones consisted also prevented the water from adhering to them, and caused the stones to be surrounded with a concave meniscus, which naturally may have contributed to, and perhaps was the main cause of their floating, which sometimes was further facilitated by a patelliform shape of some of the bigger stones."

The floating sand of the Llano showed upon careful examination no signs of the presence of low forms of vegetable growth, neither was it in the least greasy. That the presence of oil in a bituminous shale may facilitate its floating property can scarcely be doubted.

Nature for February 1, 1900 (p. 318), contains two communications upon 'Floating Stones' by Messrs. Cecil Carus-Wilson and R. C. T. Evans, respectively.

Most of the points made by Mr. Carus-Wilson are covered in the papers of Messrs. Graham, Ladd and myself. It may, however, be of interest here to call attention to the following. He says:

"The grains float as patches composed of fine and coarse material clinging together; the presence of the very fine grains appears to facilitate the flotation of the larger grains and shells."

As bearing on this statement I will quote briefly from my paper:

"As I was sprinkling some sand upon the river for experimental purposes, a pebble almost as large as the end of my little finger fell into the center of a floating patch, which, to my great astonishment and delight, was depressed, like a funnel, for, say, half an inch before the cause of this unexpected phenomenon broke through its surface and sunk to the bottom" (p. 35).

His statement regarding the formation of 'patches' had also been anticipated in my paper (p. 36).

Mr. Evans writes that he has observed the phenomenon of floating stones at Kimmeridge, where the flaky nature of the beach material renders their appearance very common.

In experimenting with broken roofing slate he found that a small dried piece $1.5 \times .75$ cms. by about 1 cm. floats easily on water when gently placed on the surface.

It will be seen from the above statements that all observers agree that to float, the sand or stones must be lightly launched without complete wetting.

SEA-BIRDS A SANITARY NECESSITY.

This country is on the verge of losing forever one of the main features of its seacoast charms—the sea-birds themselves. In fact, the Terns, the most exquisite of the Gull family, which formerly thronged our whole coast, have been so nearly wiped out by agents of the milliners that this year's onslaught, already fully organized, will glean almost the last pair from the few small breeding colonies which remain, wherever these are unprotected. And the larger Gulls, which are not only very beautiful, but absolutely essential as harbor scavengers, are also being decimated for the same purpose.

All these species, with their exquisite beauty, their wild voices and their most romantic lives, peopling a realm which, without them, would be oppressive in its dreary grandeur, will reach their breeding places in a few weeks, and the Terns, especially, are liable to be slaughtered the moment they get there; therefore the promptest action is necessary, if we are to save even the few pairs of the latter which could restock our devasted coast when the evil eye of fashion shall have turned to other victims.

Simple economic considerations make it a matter of course that the Gulls *must* be saved. An immense horde of them, which naturalists think number anywhere from a hundred thousand to a million, gorge twice a day in New York Bay upon garbage. As the hour of the 'dump' approaches, their multitudes fill the whole air to an immense height, over an area of several miles, then gradually settle on the sea in vast white sheets. The whistle of the police boat, the signal to 'dump,' seems to waft them simultaneously into the air, to gather, like dense snow clouds, over the floating masses just emptied from the many scows.

Imagine from what an amount of putrid matter these birds, as big as hens, save the adjacent beaches, not to speak of their perpetual gleaning in the actual harbors! And this is a specimen of what occurs at every port. And shall this incalculable sanitary benefit, and all this beauty, terminate forever, and for no worthy purpose?

If money enough can be raised, the Committee of the American Ornithologists' Union will guard every breeding place where there is a law to back them, as Mr. Mackay and Mr. Dutcher have done at Vineyard Sound Islands and Great Gull Island. The utmost caution will be used in choosing wardens, and the Committee will be glad to receive names of men especia ly suited for the post. Light-house keepers and Life-Saving Station captains will be employed wherever feasible. A very encouraging sum is already in the hands of the Committee.

The places to be protected are certain islands on the coast of Maine, Long Island, New Jersey, Maryland, and perhaps Virginia and Florida. In Maine alone there is need of all the money we can possibly get, since there single wardens are afraid to face the rough plumers, and some more elaborate organization is the only hope.

The American Ornithologists' Union therefore appeals to every bird-lover for money to be used in hiring wardens to protect the birds while nesting. Contributions should be sent to Mr. William Dutcher, treasurer of the Union, at 525 Manhattan avenue, New York City, who will furnish all desired information.

NOTES ON ELECTRICAL ENGINEERING.

A NEW INDUSTRIAL SITUATION.

IN a pamphlet recently issued by the Westinghouse Companies, Mr. Geo. Westinghouse calls attention to the prospective use of the gas engine on a great scale for the generation of power and, in connection with central gas plants and pipe lines, for the distribution of power. Mr. Westinghouse says that "long familiarity with the electrical industry, the pipe line transportation of natural gas in great quantities, and an active interest in the development of large gas engines, satisfy me that the great economies which will result from the distribution of power by means of gas generated at central points, and conveyed in pipes along the lines of railway for the operation of gas engines and electric generators, will be sufficient to justify the expenditure of the capital necessary for such installations in connection with the electrical equipment of railways, particularly metropolitan and suburban lines. The advantages of the use of gas engines can be best appreciated when it is understood that if a gas company were to supplant the present gas illumination by an equal amount of electric light obtained from gas-driven dynamos, it would have left for sale or other purposes over 60 per cent. of its present gas output."

In a communication to the New York *Times* of January 10, 1900, Mr. Westinghouse suggests the employment of fuel gas and gas engines for supplying light and power to the whole of Manhattan Island. He calls attention to the fact that city garbage is much better adapted for the manufacture of fuel gas than for use under a steam boiler, the large percentage of water in garbage being little or no disadvantage in the manufacture of fuel gas. He mentions the fact that fuel gas manufacture is a smokeless process, and he points out that the water consumption of gas engines may be kept far below that of steam engines. "Bearing on these questions" says Mr. Westinghouse "and of especial importance, are the partially executed plans of the electric power and light corporations, viz, the Metropolitan, Third Avenue and Manhattan Elevated Railways, the New York Gas and Electric Light, Heat and Power Company, and the United Electric Light and Power Company. If their present plans, which are fairly well known to the engineering profession, are carried to completion, each will have one large steam station on the East River between Twenty-ninth street and the Harlem River, with about 75,000 horse-power of engines, boilers, and electric machinery, making an aggregate of 375,000 horse-power, and which may be largely increased when the underground rapid transit railway is completed, and still further when the electric locomotive is used on all steam railways within the city limits.

"If these corporations were to unite in a common plan to provide the electricity needed in their operations by the adoption of the best available methods, the saving to each in capital expenditure would be very great, and the decreased cost of their supply of electricity would make an important addition to their earnings applicable to the payment of dividends; while, most important of all, the citizens of New York would have solved for them the garbage, smoke, and very largely the water questions.

"I believe the contemplated plans of the corporations above named, which can be shown to be based upon an imperfect knowledge of the subject, will stand in the way of vast public interests, and, so believing, I have said to representatives of some of these companies that the near future would demonstrate the projected power stations and systems of electrical distribution incidental to the character of such stations, to be as far from the best as are the old cable systems for the propulsion of cars."

It seems to the present writer that the recent improvements in the gas engine and the consequent commercial possibility of its use on a vast scale in the transmission and generation of power, warrant the title of the pamphlet issued by the Westinghouse companies 'a new industrial situation,' and it is a matter of especial satisfaction that the plan proposed by Mr. Westinghouse for New York City which promises such great benefits to the community, also commends itself to the business interests of the corporations concerned. Mr. Westinghouse's plan is entirely sound, at least the scientific and technical points involved are clear and certain, and it should engage the attention of every public spirited citizen.

WIRELESS TELEGRAPHY.

The Transactions of the American Institute of Electrical Engineers for December, 1899, contains an interesting discussion on wireless telegraphy. Professor R. A. Fessenden, in particular, describes some interesting experiments by himself and Professor Kintner. These two experimenters being unable to use the ordinary coherer as a measuring instrument, devised a small induction galvanometer (originally due to Elihu Thomson) for measuring the intensity of the electrical waves at the receiving station, and this induction galvanometer is said to be more sensitive than the coherer and well adapted as a receiving instrument in practice. Professor Fessenden also gives a good description, based upon the mathematical work of Hertz, J. J. Thomson and Heaviside, of the character of the electrical waves which pass out from the vertical wire at the sending station; he calls attention to the rational basis for Marconi's law, or rather a modification of Marconi's law, that the range of signalling in miles is proportional to the product of the heights of the vertical wires at the sending and receiving stations, and explains why longer distance signalling is possible over water than over land. Those who are interested in this matter will find Professor Fessenden's discussion instructive and interesting.

Long distance wireless telegraphy seems to be now almost within reach, with high sending and receiving wires and with very powerful electrical disturbances at the sending station, very slight improvements in the sending and receiving apparatus will likely carry the range up to a thousand miles or more.

CURRENT NOTES ON PHYSIOGRAPHY.

IOWAN DRIFT.

CONTINUED studies of the drift of Iowa by members of the State Geological Survey give new details regarding the topographic differences between the three chief drift sheets (Kansan, Iowan and Wisconsin), indicative of their differences of age. Calvin describes the Iowan drift sheet (*Bull. Geol. Soc. Amer.*, x, 1899, 107–120) as forming a broad plain of long, gently sweeping undulations, on which stream erosion has in general done little work; only the main drainage lines, many of which follow sags in the drift that are taken to indicate pre-Iowan valleys of erosion, are well defined; small lateral channels have been eroded only a mile or so from the main valleys. In contrast with this little carved surface, the Kansan sheet, next south, was maturely and deeply eroded before the Iowan sheet was deposited. The Kansan-Iowan interval is thought to have been fifty times the post-Iowan period. About the middle of the latter period is taken as the date of the lobe of Wisconsin drift that enters from Minnesota and overlaps both the Iowan and Kansan sheets. The surface of this lobate area shows even more distinct signs of youth than are found in the Iowan area; undrained depressions are of frequent occurrence on its undulating prairies; oxidation and leaching have hardly begun; stream erosion is insignificant. The value of topographical evidence as indicating geological dates is seldom better illustrated.

The same author described 'a notable ride' from the driftless area of northeastern Iowa to the Iowan drift sheet, where the contrasts of a maturely dissected upland of normal development, and the broad swells and troughs of a till plain are well presented (*Amer. Geol.*, xxiv, 1899, 372–377).

WESTERN AUSTRALIA.

AN account of part of western Australia by Cadell ('Some geological features of the Coast of Western Australia,' *Trans. Edinb. Geol. Soc.*, vii, 1897, 174–182) ascribes the absence of harbors to a recent slight elevation after prolonged denudation. The elevation is indicated by raised beaches, now 10 or 15 feet above sea level, one beach being from 12 to 18 miles wide and reaching 25 miles inland. The beaches lie on a low, flat plain of denudation, monotonous and desolate, sloping imperceptibly to the sea. An inland excursion of seventy miles was chiefly over a perfectly flat surface of granite, clay slate and other rocks, strewn with wind-worn pebbles and relieved by occasional crystalline knobs which rise over its prairie-like expanse. No mention is made of incised valleys; the few water courses of the region, usually with dry beds, seem to lie but little below the general level. The rocks are as a rule deeply weathered; water being commonly found in wells at depths of 45 or 50 feet. The inland termination of the plain is not described. The possibility of accounting for such a plan by subaërial or by marine denudation is recognized, and a preference is expressed for the latter agency in this case (although the deep weathering of the rocks seems to be more accordant with a subaërial history). A comparison is made between this denuded lowland and the flat pavement on which the Cambrian rocks of northwest Scotland rest; it is further suggested that if the Australian plain were scoured by glacial action, it would be transformed to a hummocky surface, resembling the 'rough quarter' of the gneissic uplands of Sutherland (N. Scotland).

MOUNTAINS AND VALLEYS.

Richter of Graz writes on 'Gebirgshebung und Thalbildung' (*Zeitschr. deut. u. österr. Alpenverein*, xxx, 1899, 18–27), re-affirming the modern view that the bold forms of the Alpine summits result from the carving of valleys between them. He calls attention to the rough equality of height among the peaks of the Alps, and discusses the relation of peak height to valley spacing. He points out that in lofty ranges, the valleys must be relatively far apart, in order to allow the intervening mountain to rise to a great height. Before the greater uplift of the Alps, when the relief of the surface was less, streams and valleys were probably more numerous and closer together. As elevation progressed, some streams deepened their valleys faster than others and the side branches of the more active streams tapped the less active streams at many points and practically destroyed them; thus only the stronger streams survived in the deeper valleys. The rapid erosion of cliffs has reduced the mountain sides to a relatively uniform declivity, and the peaks are defined by the intersection of slopes propagated upward from the stream lines. Glacial action is briefly referred to as having produced trough-like channels whose side walls are steeper than the preglacial valley slopes which rise above them.

THE MEUSE IN BELGIUM.

After the Meuse trenches the Ardennes, it turns eastward along the strike of the Carboniferous rocks, receiving the Sambre from the western extension of the same geological belt. On this longitudinal course, streams of considerable length are received from the valleys of the Ardennes on the south, but the divide on the north lies close to the Sambre-Meuse, except at a few points where it locally loops northward. The streams that drain these loops receive a number of barbed headwaters which flow away from the Meuse valley before turning around towards it. The barbed headwaters are explained by Cornet as having once belonged to streams that flowed continuously northward. They have been captured by side streams of the Meuse in consequence of the depth to which its longitudinal valley has been cut (*Ann. Soc. géol. de Belgique*, xxvii, 1899). The beheaded streams, northward of their diverted headwaters, and their special relations to the valleys that they occupy are not described.
